In a number of individuals examined by the writer the endurance of the orbicularis oris was found to be decidedly below normal; at least this was true of those instances of depression (melancholia) in which the somatic symptoms were at all prominent. Again, and of similar drift, is the fact that the same phenomenon was observed to follow the exhibition of large doses of alcohol and the bromides, the amount of the latter being sufficient to cause pronounced mental hebetude. A like effect also occurs some time after the inhalation of ether, and this despite the fact that the subject has sufficiently recovered from the anesthetic to stand and even walk. Incidentally, it may be remarked that the vacuous expression of the face so frequently met with in typhoid fever, due, as it is, to relaxation (hypotonicity) of the facial muscles, coincides with pronounced loss of endurance of the ring muscle of the mouth. Finally, as previously noted, we have the significant fact that in the diffuse meningoencephalitis of paresis, loss of endurance of the ring muscle of the mouth is met with rather early.

From the foregoing data the following conclusions would seem to be justified:

1. General conditions that tend to lessen the energy of the cerebrum as a whole and of its cortical (motor) neurons in particular will express themselves rather more promptly in the muscles of the face than in other parts of the motor system.

2. The kinetic condition of the orbicularis oris muscle may be regarded as indicative of that of the other facial muscles under the circumtances set forth under 1.

3. The voluntary and involuntary mechanisms of expression, while structurally independent, are both amenable to the general influences noted under 1, so that the degree of endurance disclosed by the orbicularis oris, when voluntarily contracted in the manner previously set forth, may serve as an index of the efficiency of innervation of that muscle, and hence of the other muscles of expression, when, under emotional incitement, the latter are involuntarily (reflexly) contracted.

4. In emotional depression, especially when somatic symptoms are a marked feature, loss of endurance of the ring muscle of the mouth is a sign of some importance.

5. From the foregoing it follows that under certain circumstances, and more especially when associated with other signs, the degree of endurance revealed by the orbicularis upon voluntary contraction may afford confirmatory information as to the subject's emotional condition.

6. In diffuse meningoencephalitis occurring in general paralysis of the insane, loss of voluntary endurance of the ring muscle of the mouth occurs fairly early.

7. The endurance of the orbicularis may be enhanced or diminished by the exhibition of certain drugs; enhanced, for example, by small doses of opium and strychnine; diminished by relatively large doses of nicotine, alcohol, ether, and the bromides.

8. The orbicularis phenomenon which forms the burden of the present writing will, the writer believes, prove most informing when associated with other symptoms. Only exceptionally, it would seem, is it likely to prove of assistance when unsupported by further evidence.

Many signs, empirical and rational, have been added to the symptomatology of nervous affections during the last few years. Some of these have held their own in the estimation of the profession; others have failed on more extended trial to maintain themselves. In view of these happenings it is not, perhaps, the part of wisdom to warm too ardently to new proposals; but neither, on the same evidence, is it policy to flout them. This judicial attitude the writer has sought to maintain toward his own work; and it is far indeed from his thought to bespeak either a more sceptical or yet a more rhapsodistic mood on the part of the reader.

53 West Thirty-eighth Street.

A CASE OF DENTAL DEVELOPMENTAL ANOMALIES, WITH CYST FORMATION.

By CECIL KENT AUSTIN, M.D.,

PARIS, FRANCE.

Cases like the following one appear to be extremely rare; such was at least the unanimous opinion of the three confrères to whom I showed it—a surgeon, a radiologist, and a dentist, all of them men of the most extensive and varied experience—no one of whom had ever seen anything similar. It consequently seems to be of sufficient interest to aspire to the honors of the medical press.

The patient, a young Scotch woman of twenty, presented every appearance of a person in the best of health. A peculiarity in her development has been that three teeth in the lower maxilla have always been lacking, at any rate in her second dentition; whether there were any dental anomalies in her childhood she does not of course remember. The teeth missing in this maxilla are: on her right side, the second bicuspid and a molar (uncertain whether first or second); on her left, the first molar. In the upper maxilla all of the teeth came out properly, though she has since lost two from decay. She has only one wisdom tooth, in the upper maxilla on the right side. Otherwise her teeth are sound and in good condition.

Three years ago, consequently when she was seventeen, a swelling began to make its appearance just behind her only lower molar on the right side. This lump increased in size very gradually but caused her no discomfort whatever, except such as was due to its presence and bulk; she was in the habit of pressing on it frequently through her cheek from the outside. It finally became so voluminous as to overcap the molar that lay in front of it. There had never been any signs of the eruption of a wisdom-tooth at this point, nor had she ever had any trouble there of any description.

At the end of a year's time the swelling appears to have passed through an acute phase of inflammation of about a week's duration, after which it opened and allowed a certain amount of "matter" to escape, red, according to the patient's description; but more precise information about this period it was not possible to obtain, as the woman was anything but an accurate observer.

By the time that the acute accidents had subsided the patient found that a cavity had formed just behind the molar, and this cavity proved to be a per-

manent one, and even, according to her affirmation, has been gradually growing larger and larger. She seeks advice solely on account of the fact that food gets into this cavity and renders her breath offensive; there is no pain whatever in the region and no

Fig. 1.—The solitary lower right molar, back of which is seen the large, deep cavity.

other inconvenience arising from the presence of this anomaly.

On local examination of the posterior portion of the right side of the lower maxilla the first abnormal feature that appears is a breach in tooth succession back of the first bicuspid, in which she affirms that no teeth have ever existed; this gap is quite extensive, more so than seems likely to be attributable to the absence of a tooth no larger than a bicupsid. Back of this stands a fine, fully-developed molar in perfect condition. Back of this again, and occupying all the posterior portion of the horizontal branch of the maxilla, is a dark, deep cavity into which a small hickory-nut could be inserted. The interior of this cavity is considerably larger than its opening into the mouth, and at its anterior aspect the posterior roots of the large molar are laid bare. The mucous membrane covering the exterior of this hollow is normal in appearance. On exploring the cavity with a probe no grating is felt, the inside being apparently lined with a granulating membrane, as the patient says that each morning there is a small quantity of red secretion in the hole. This exploration causes no pain whatever.

On the outside of the face the lower edge of the maxilla is normal and similar in all respects to that of the opposite side; its external aspect, however, protrudes somewhat, with a hard and even surface, over which the soft tissues can be freely moved. No discomfort is caused by external exploration. The lymph-nodes are not involved. The patient gained three or four kilos in weight last year, but has lost them again since.

The accompanying illustration (Fig. 1) from a photograph which, although not very remarkable, was the best that could be obtained under such difficult circumstances for the operator, gives a general idea of the appearance presented by the lesion.

Radiographic examination was carried out a few days later and revealed various interesting and important features. Fig. 2 showed that there were no non-erupted teeth included in the substance of the lower maxilla between the right bicuspid and big molar. Fig. 3 brought to light a new and unexpected detail: the presence in the posterior end of the pathological cavity of a large buried tooth lying quite horizontally and fastened in the substance of the ascending portion of the maxilla. Between this tooth and the large molar can be seen the faint shadow due to the loss of tissue, surrounded by a heavier shadow, which was found later on to be caused by extreme bone-condensation around the cavity. Both of these plates are due to the courtesy of Dr. J. Belot, whose competence in matters of this kind is well known.

Once in possession of these data our next step was to try to formulate a diagnosis; but as we were manifestly in presence of a case of anomalous tooth-eruption, it was clear that the best that we should be able to accomplish would be to make more or less likely suppositions. Before the radiographic exploration we thought that we were dealing with a cyst developed at the expense of the germ of a wisdom tooth, though the early age at which the accidents occurred did not seem in entire accordance with this theory. When, however, the existence of a fully developed tooth was demonstrated in the depths of the cavity we had to give this idea up, as it seemed most probable that that was the wisdom tooth hidden away behind there. We then turned to the hypothesis of a cyst caused by degeneration of the germ of the second molar. It is true that the space between bicuspid and molar was pretty large, much larger than could possibly be due to the absence of one normal, second bicuspid; but we thought that possibly the first molar might have gradually sagged backwards, giving way before the masticating-thrust falling on a tooth unsupported either front or back. Again, the idea occurred to us that, as we were dealing with anomalies of all sorts, why should this not be in reality the first molar considerably out of its appointed position?

But the extent of that gap between bicuspid and molar continued to weigh on our minds, and the theory that the molar to be seen must be the second gained steadily in ground. This was also borne out by the fact that the molar lacking on the opposite side was the first one and there seemed a certain possibility that the anomaly might be symmetrical. If this supposition were the correct one the pathological condition could only be explained by an infectious process accompanying the evolution of the hidden wisdom tooth. And this was as far as we could get, no means occurring to us of deciding which of the two hypotheses was the correct one, cyst of the second molar or infectious process due

Fig. 2.—X-ray from inside out, of anterior portion of patient's lower maxilla, right side, showing that there are no included teeth in that region.

to the wisdom tooth. It was, however, decided to remove the entire diseased area under chloroform.

This proved to be much more difficult than any one anticipated. The soft tissues were first freed all around the swelling; but although the operator,

Dr. Du Bouchet, surgeon to the American hospital here, has a powerful grip and had provided himself with the strongest cutting forceps available, the bony wall of the cavity was so dense and hard that nothing whatever could be accomplished with that instrument. A start, however, was finally effected with a gouge and mallet and gradually, by using first one instrument and then the other, the entire morbid process was cut away, the wisdom tooth coming out in the meantime—sufficient bony tissue remaining below the gap created by the operation to insure the solidity of the maxilla. The sequelæ to the intervention presented nothing worthy of note and the whole region healed over most satisfactorily.

Fragments of the wall of the cavity were taken

and placed to decalcify in order to obtain stained sections to settle the point as to whether by any chance there might be any element of malignancy in the process; but the density of the bone was such that although the pieces were treated in a variety of liquids it was found impossible, even in several months, to decalcify the specimens, and the attempt had to be abandoned. Our minds, however, were set quite at rest on the malignancy question by the course of events as time went on, and a year after the operation the patient is entirely well. The tissues over the operated region are now perfectly normal and the young woman is about to have a plate made to supply the missing teeth, as she has nothing to masticate with on that side of the lower maxilla back of the first bicuspid.

How to Avoid a Chauffeur's Fracture.—Eliminating the possibility of abnormal overheating of the engine, such as might follow an accident to the cooling system, the best way to avoid a back-firing while cranking is to make sure personally that the spark lever is properly retarded. However, there is one method whereby, even with the occurrence of a back-fire, little or no injury can be sustained. This is to crank the engine with the *left hand*. Should a back-fire occur, a glancing blow will be received, which, if painful, is unlikely to do serious damage.

SURGERY OF THE HYPOPHYSIS WITH ESPECIAL REFERENCE TO THE ENDO-NASAL METHOD OF HIRSCH.*

By IRVING WILSON VOORHEES, M.S., M.D.

NEW YORK CITY.

The interest of the profession in the relation of pathological changes in the hypophysis cerebri to general disturbances of body nutrition and growth, has been greatly stimulated since P. Marie in 1886 published a report of two cases of acromegaly which he ascribed to disease of this little understood but seemingly important organ. The term "hypophysis cerebri" had, however, been previously used by Soemmering in 1778.

Physiological and Anatomical Considerations.—Sir Victor Horsley is credited with the first experimental operations on the hypophysis. He removed this organ from two dogs, which lived respectively five and six months without showing any symptoms. Subsequently he stimulated the cerebral cortex and found increased excitability of the motor regions. Faradic currents of moderate strength produced a marked tetanus, followed by severe protracted epilepsy with clonic spasms fully as strong as those in traumatic epilepsy in man.

It seems that the life of an animal deprived of the hypophysis may be prolonged for some time, but that death is the ultimate outcome of the removal of this gland. Cushing removed the hypophysis from many dogs and then either injected or transplanted the gland from other animals. He is convinced that total removal leads to a definite train of symptoms, which can be modified by gland injection and transplantation. He is led to believe that the anterior lobe is the most essential part of the gland and is necessary to life. Adiposity is the most pronounced symptom after partial removal of the anterior lobe. This is accompanied by a secondary hypoplasia of the genital organs in adults or by a persistence of secondary infantilism if removal antedates adolescence.

Gley found that of ten rabbits deprived of the hypophysis only one survived the operation. This animal had previously undergone a complete thyroidectomy. For three weeks following the removal of the hypophysis the rabbit presented at intervals a series of slight complications, but survived the more important trophic disturbances, such as thickening of the skin and marked asthenia, for a period of ten and one-half months.

Vassale and Sacchi removed the hypophysis from forty cats and dogs. These authors are of the opinion that the complete removal of the hypophysis leads to death, prior to which the animal gives evidence of great psychical depression and marked change in disposition.

The majority of frogs from which the hypophysis was removed died in the course of a few

*Read at a meeting of the Section on Rhino-Laryngology of the N. Y. Academy of Medicine, May, 1912.

In the preparation of this essay I have made free use of the admirable monograph of Dr. Frederick Tilney of the College of Physicians and Surgeons (N. Y.) and of Dr. Hirsch's published reports, the first of which appeared in the *Archiv für Laryngologie*, 24 Bd. 1 Heft. The latest contribution from Dr. Hirsch's pen was published in the *Berliner klinische Wochenschrift*, 1911, No. 43. In a private letter in which I was requested by Dr. Hirsch to translate as much of his reports as seemed desirable, he informs me that he has operated upon eighteen cases thus far, with only two fatalities, one of which was due to pneumonia.

weeks with symptoms of progressive paralysis. Autopsy showed a purulent basilar meningitis.

Berkley studied the nerve elements in the hypophysis of dogs. He concluded that the organ has retained its double rôle of secretory and nervous

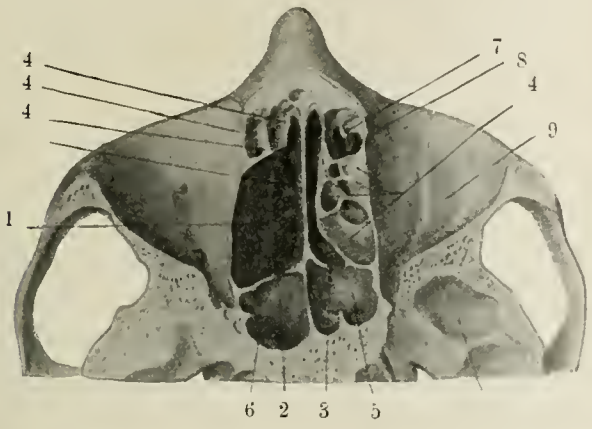

Fig. 1.—Horizontal section through the skull at the level of the ostia sphenoidalia. On the left side the posterior and in part also the anterior ethmoid cells are removed. The anterior wall of the left sphenoidal sinus is exposed. The normal anatomical relations are represented on the right.

function intact, the former perhaps modified, the latter or original special sense organ probably lying quiescent and only changed in so far as to admit of a slightly different arrangement of its elements.

There can be little question that the infundibular process takes origin from the brain while the glandular portion arises from the epithelium of the mouth cavity. Certain bodies known as basophilic elements are formed in the posterior portion of the gland and probably pass into the cerebrospinal fluid by way of the third ventricle. In the anterior portion of the gland acidophiles are formed which probably pass directly into the blood. Colloid substance has been observed in the gland. A rich vascularization in the granular portion of the hypophysis has been recognized by all observers. No definite lymphatic supply has been proven.

The relation of the thyroid to the hypophysis is uncertain. It was at one time thought that one was the counterpart of the other, but Rogowitsch made a series of studies upon animals from which the thyroid had been removed. In dogs and rabbits he observed a constant hypertrophy of the hypophysis, and for this reason believes that this organ and the thyroid gland are closely related in function and that, like the liver, it contributes a substance to the

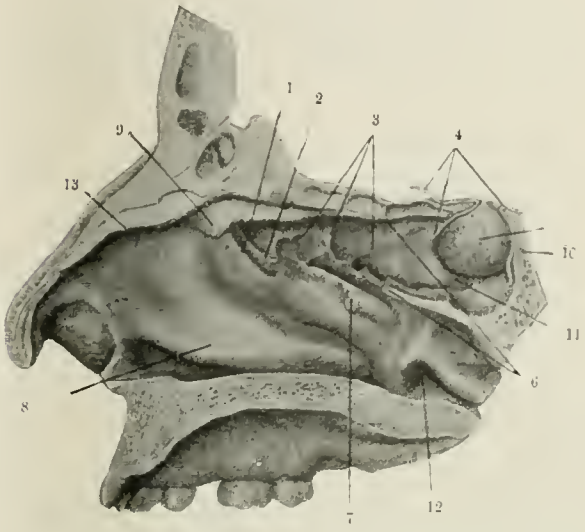

Fig. 3.—Endonasal hypophysis operation dependent upon the wide opening of one sphenoidal cavity only. Right half of the nose with the hypophysis tumor *in situ*. blood which renders certain compounds innocuous.

From a clinical standpoint, there appear to be good reasons for associating hypophysis disease with acromegaly, but the following objections hold: (1) Sixty reported cases of acromegaly showed only 61 per cent. with hypophysis tumors (Arnold).

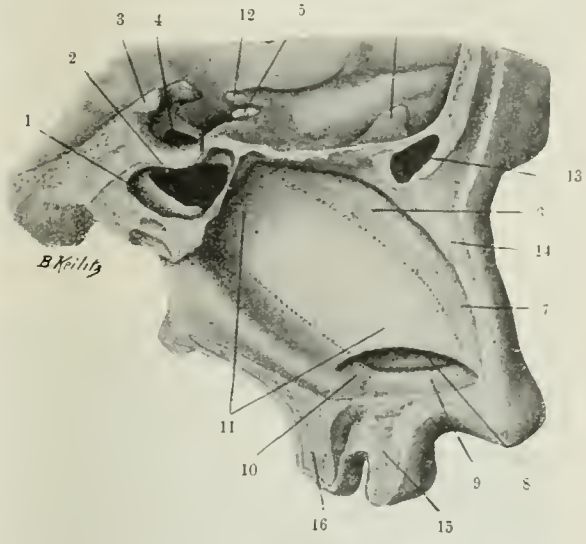

Fig. 4.—Endonasal hypophysis operation dependent upon the submucous resection of the septum. (The skull was sawed through to the right of the middle line so that the entire left sphenoidal cavity is seen and a part of the right.) The septum between the two cavities has been removed in great part. In the floor of the sella (normal) an opening has been made.

Proc. clin. anter. 13. Frontal sinus. 14. Bony bridge. 15. Upper lip. 16. Proc. alveolaris. (After Hirsch.)

(2) Changes in the hypophysis may occur in the course of some acute and chronic diseases (Thom). (3) The pathology of acromegaly includes many other organs and systems besides the hypophysis

and bones (Arnold). (4) Changes in the bones and soft parts have been observed as secondary to certain respiratory and circulatory diseases (Marie). (5) Tumors of the hypophysis frequently exist without any symptoms of acromegaly.

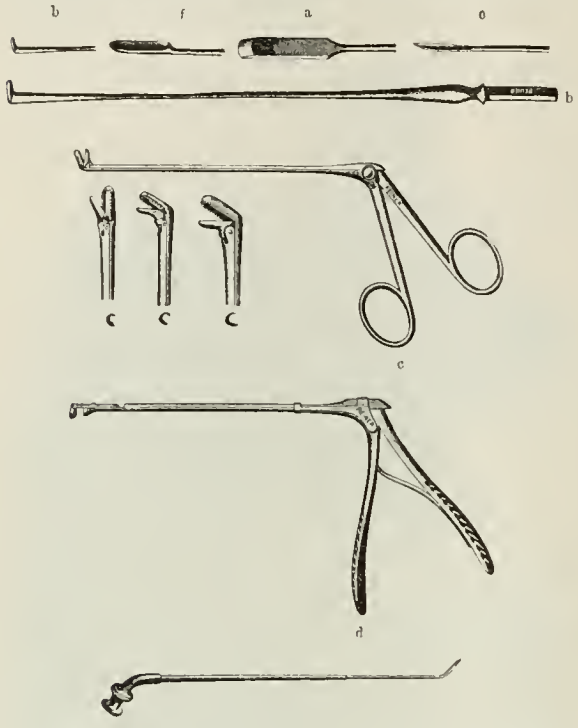

Fig. 5.—Instruments used by Hirsch in the hypophysis operation: *a*, chisel; *b*, large and small right angled elevators; *c*, straight and upward curved bone forceps; *d*, bone rongeur; *e*, knife for incising the dura; *f*, curette; *g*, needle for infiltration of the anterior sphenoidal walls. (Three-fourths natural size.)

Tilney concludes that the hypophysis is probably functionally active, but that the significance of the neural lobe has not yet been determined. There is, perhaps, sufficient evidence to show that the secretory product of the basophiles passes into the cerebrospinal fluid, while that of the acidophiles enters the blood. There are two groups of investigators. One group contends that the hypophysis is indispensable to life and that its removal causes a definite symptom complex which rapidly leads to death. The other group is directly opposed to this and believes that the hypophysis is entirely rudimentary and without function.

Fig. 6.

The relation of the hypophysis to the brain membranes is important. The hypophysis possesses no pia or arachnoid, but lies in a pocket which is formed of two layers of dura, namely, the diaphragm sellæ and the dural covering of the saddle fossa. The delicate brain membranes cover only the stalk of the hypophysis and reach only as far as the diaphragm sellæ. Therefore, in the hypophysis operation the subarachnoidal space is not opened. The anterior lobe develops from the mouth cavity and ascends from the roof of the pharynx to attain its final position. Thereby it is explained why one finds hypophysis tissue so constantly present in the vault of the pharynx, which Erdheim called "the pharyngeal hypophysis."

There are three forms of disease (tumors) of the hypophysis:

(1) Acromegaly, described first by Pierre Marie in the year 1886, which manifests itself by an increase in size of the hands, feet, nose, and tongue, and in thickening of the lips. It is usually associated with disturbances in the function of the sexual glands and disturbances of vision may also be present.

(2) Degeneratio adiposogenitalis, a disease picture which Fröhlich first described from the Ambulatorium of von Frankl-Hochwart in the year 1902. It exhibits a fatty degeneration of the organism, usually acompanied by disturbances in the function

Fig. 7.

of the sexual glands and trophic disturbances, such as loss of the beard, and of the hair in the axilla and on the pubis. Disturbances of vision may also be present here.

(3) Disturbances of vision without striking general symptoms. The disturbances of vision may advance to total blindness. Usually there is also an alteration in the function of the sexual glands, and frequently slight struma is found. Headache may be present in all three forms of disease in varying intensity, but may also be completely absent. It is interesting and important that acromegaly is associated with tumors of the anterior lobe, and, as Benda showed, chiefly with adenoma or adenocarcinoma. Most probably a hypersecretion is present.

The disease-picture of degeneratio adiposogenitalis may be produced by other tumors. According to Erdheim, the tumor is not in itself the cause of fatty degeneration, but pressure against a center which Erdheim supposes is situated at the base of the brain and Fischer in the posterior lobe of the hypophysis.

The diagnosis of hypophysis tumor is based upon the determination of acromegaly or fatty degenera-

tion occurring with disturbances of sexual function, and with visual and trophic disorders. The disturbances of vision in hypophysis tumors show a diminution of the acuity of vision and contraction of the visual field in the form of bitemporal hemianopsia. The latter when present to a severe degree should arouse a suspicion of hypophysis tumor. An extremely important aid in the diagnosis of hypophysis tumors is the *x*-ray, as Oppenheim first pointed out, since it makes possible the determination of the hollowing out of the saddle by the tumor. However, the *x*-ray determination of the hollowing-out process is not alone sufficient to diagnose hypophysis tumor, since this picture may also be produced by other diseases, for example, diffuse or circumscribed hydrocephalus complicating a chronic circumscribed meningitis, and other tumors in other parts of the brain. Headache, sleeplessness, and low temperature are frequently present, but are not constant in hypophysis disease. The treatment of hypophysis tumors like the treatment of other tumors is only surgical. Thyroid tablets, iodine, and hypophysin tablets have only a transitory influence. The operative methods are either intracranial or extracranial. Horsley was the first to undertake the hypophysis operation. He operated by the intracranial method through the middle fossa of the skull. But this surgical attack signifies nothing, since a short description but no certain statements are given concerning the result obtained. A second intracranial route carried out through the anterior cranial fossa was described by Krause. However, in so far as I know, he did not operate upon the hypophysis but removed in one case a foreign body (projectile) from the sella region, and in another case a fibrosarcoma from this region, the latter operation being followed by a fatal termination.

Surgical Considerations.—Schloffer, in the year 1906, published a paper concerning operations on the hypophysis, in which he discussed thoroughly the physiology and pathological anatomy of the hypophysis and came to the conclusion after study of all the known operative methods for exposure of the hypophysis that the extracranial methods are the easiest and most satisfactory to carry out. As a matter of fact, one year later, 1907, Schloffer operated upon a patient for hypophysis tumor, under general anesthesia, by the nasal route and succeeded in a partial removal of the tumor. He made his incision on the left side of the external nose and turned the entire nose toward the right. He then removed all turbinates on the left and the septum, after which the inner wall of the left antrum of Highmore and a part of the nasal process of the left upper jaw were taken away. After exenterating the ethmoid cells, he opened the sphenoidal sinus and removed the posterior wall of the sinus, gaining direct access to the tumor.

The patient operated upon by Schloffer withstood the operation very well, but died two and one-half months later from symptoms of brain pressure. Hochenegg was the first to operate upon a patient with acromegaly and to show the satisfactory result in that the symptoms caused by the hypophysis enlargement decreased. Since that time the operation has been performed by various general surgeons, among them von Eiselsberg, in this or in a modified form until at the present time (1911) it has been carried out fifty-three times, thirty-seven with a good result and twenty-one with a fatal issue. The mortality amounts to 39.6 per cent.

The operative results demonstrated: (1) that the exposure of a hypophysis tumor according to Schloffer's method was not especially difficult; (2) that meningitis does not necessarily take place, in spite of the fact that the tumor is directly exposed to the air in the depths of the nasal cavity; and (3) that the partial removal of the hypophysis gives no appreciable disturbance, but on the contrary in cases with trophic disturbances and acromegaly favorable results are to be obtained.

In thirty cases operated upon by the Schloffer method, or after the same principle, there were eleven deaths, three of which were due to meningitis, one to aspiration pneumonia, and the other deaths were supposedly caused by prolonged narcosis and great loss of blood.

Hirsch says: "I followed the development and the results of Schloffer's method with very great interest when I saw that the general surgeon was attacking the region which for a long time had belonged to the rhinologist. It was to me, as a rhinologist, perfectly clear that the nucleus of the Schloffer operation lay in working within the sphenoidal sinus, and that the great surgical attack upon the external and internal nose only served to afford a wide exposure of the sphenoidal sinus; and, moreover, that this preliminary manœuver necessitates the lengthy narcosis and the severe bleeding which during the operation may produce asphyxia and after the operation endangers the life of the patient through anemia, heart weakness, and pneumonia. The exposure and wide opening of the sphenoidal sinus is, however, a measure which can be carried out by the rhinologist by the endonasal route under local anesthesia without very much bleeding. It seemed possible, therefore, that after opening the sphenoidal sinus the rhinologist could also easily reach the tumor."

Hirsch saw that it was impossible to remove a hypophysis tumor completely by Schloffer's method, as was proven in Schloffer's first case, which died two and one-half months after operation, and in which the tumor was seen to have been only partly exsected. An especial difficulty which is mentioned by Schloffer and also by von Eiselsberg seems to have been orientation in the depths of the wound owing to the difficulty of establishing satisfactory landmarks and also because of the bleeding into the wound. With these disturbing and unsatisfactory elements in mind, Hirsch says: "I came to the conclusion that removal of hypophysis tumors could be carried out by opening the sphenoidal sinus endonasally, and that this exposure must be carried out in two operative acts: (1) wide opening of the sphenoidal sinus through the nose, and (2) exposure of the hypophysis tumor by chiseling away the bone in the sphenoidal sinus and incising the dura. The method which I used in my first case was based upon the wide opening of the sphenoidal cavity within the nose, as Hajek first performed it. After opening the sphenoidal cavity, which, as is known, must be carried out in several sittings, since the middle turbinate must be first removed, then the ethmoid, and finally the anterior wall of the sphenoid, when the bony wall of the excavated sella turcica, in which the tumor lies, comes into view. This is chiseled away and its floor removed as far as possible. Thereupon the dura becomes visible and may be incised.

"Case I.—After this method, I operated upon a woman thirty-five years old in the clinic of Hofrat von Wagner on account of disturbances of vision.

A cystic hypophysis tumor was found, which I emptied, and from the wall of which I removed a small piece. The patient, who was blind in the left eye, and had in the right eye only 1/30 vision, obtained within seven months normal vision in the right eye. The left eye remained amaurotic. The field of vision also increased very markedly. The patient died sixteen months after the operation in an epileptic attack. The epilepsy, from which she had suffered for several years, had no definite connection with the tumor, according to the opinion of the neurologists. Post-mortem section showed that the cyst had not refilled. The improvement in vision was especially marked in this case and continued to the end of life. This was explained through the fact that the pressure of the tumor affected a great number of optic fibers, some of which were destroyed, and consequently improvement took place only in that part of the retina supplied by the undestroyed fibers. There was, however, no improvement in the patient's left eye because the left optic nerve was completely atrophied. The cyst was carefully examined histologically in a series of sections. It consisted merely of connective tissue ½ mm. in thickness, of a portion of the dura ½ mm. in thickness, and of a glandular portion from the pituitary body 1 mm. in thickness. The fluid which came away after incision of the cyst was of an intense bloody color and contained blood corpuscles and a brownish pigment substance. There was no sign of any malignancy."

From the report of Hirsch's first case, the completion of this work lasted about six weeks, which in the light of the newer technique was quite unnecessary. This delay occurred because it was found that after the sphenoidal sinus was opened it was not possible to reach the hypophysis tumor with the instruments at hand, and hence the work had to be interrupted until the proper instruments could be constructed. Moreover, it seemed unnecessary to expose the dura in one sitting and wait until the next before opening the same. This was done, however, at the request of Hofrat von Wagner, who considered that the danger to the patient would be much increased by splitting the dura.

Comparing the two methods, that is to say the method of Schloffer and the method just briefly sketched, the Schloffer method demanded general narcosis lasting an hour and a quarter; the endonasal method was done under local anesthesia. The Schloffer method required the difficult and disfiguring operation of removing the nose; the endonasal method no such unsightly and tedious operative attack. Moreover, in the Schloffer method there was great loss of blood, making possible only a partial removal of the hypophysis tumor; by the endonasal method there was very little loss of blood, and the exposure was equally good. The danger from meningitis was about the same in the two methods.

Hirsch found that his method was objectionable because it was carried out only on one side; that the opening to the hypophysis tumor should be carried out laterally from the middle line; that the exposure of the tumor was less sufficient than by the method of Schloffer, and finally that the danger of infection was greater. He says: "I sought, therefore, for a new method which could be carried out in a shorter time. . . . This method depends upon Killian's submucous resection of the nasal septum, but the resection is extended to the posterior part of the vomer, to the perpendicular plate of the ethmoid bone, to the rostrum sphenoidalis, to the anterior wall of both sphenoidal cavities, and finally to the sphenoidal septum. Whereupon the hypophysis tumor may be laid free in its entire extent."

The detailed technique of this second method is given under a description of Hirsch's second case, and is essentially is follows:

"*Preparation of the Patient.*—A half hour before beginning the operation the patient receives an injection of .01 morphine hydrochloride. This done, I apply 20 per cent. cocaine solution in the form of a spray to the nasal mucous membrane, and when this has become no longer sensitive I place cotton tampons soaked in the same cocaine solution in each nasal cavity. The face, external nose and chin are then washed with soap, with sterile water, and finally with benzine. The cocaine tampons are now removed and the septum and turbinates are painted with 30 per cent. cocaine solution combined with tonogen. Following this Schleich's solution No. 2 with tonogen is injected, after which the operation can be begun. By means of a syringe and with a long upward curved needle, I infiltrate both sides of the anterior sphenoidal wall and the posterior areas of the septum, and continue the infiltration of the remaining septal mucous membrane with a straight needle as far forward as the membranous septum as is done in Killian's submucous operation. I use on the whole about 2 c. cm. I wait about ten minutes for the solution to act, and meanwhile introduce cotton tampons soaked in 1 per cent. bichloride solution in the nasal vestibule for disinfection. To the left of the patient I place a table with the sterilizing apparatus and the light. On my right hand I place the instrument table and two basins with sterile water, one basin to cool off the instruments, which must be repeatedly boiled during the operation, and the second for sponging off the blood from the used instruments. Sterile gauze in strips 10 cm. long serve to wipe away the blood in the nasal cavity. Large pieces of gauze serve to wipe off the patient's face and to place the head mirror in position from time to time. Finally I have ready the necessary tampons for posterior plugging in case of bleeding."

The technique of the first part of the operation varies in no essential respect from that ordinarily used in the submucous resection of the nasal septum, as already mentioned. Therefore it is not necessary to describe it here since this operation is so well understood. After practically a complete removal of the septum it is necessary, according to Hirsch, "to expose the anterior sphenoidal wall by elevating the mucous membrane on both sides of the posterior edge of the vomer where it articulates with the sphenoid. This is done very easily, and when it is finished one proceeds with the elevation until the elevator passes through the sphenoidal opening into the sphenoidal cavity. The posterior part of the vomer and the rostrum sphenoidalis is now removed from within this mucous membrane sac and the anterior sphenoidal wall is broken through with a chisel. The opening is enlarged with bone forceps, after which the septum between the two sphenoidal cavities is removed and the posterior wall of the sphenoidal cavity is laid free. The sella turcica is then cut through with a chisel, and after splitting the dura with a knife the hypophysis comes into full view. In this way I have chiseled off the Turk's saddle in several cadaveric skulls. In some skulls in which the middle turbinate extended far toward the median line and the two mu-

cous membrane flaps on this account could not be sufficiently separated, I had to remove the free margins of both turbinates."

"Case II.—A woman forty-six years old with disturbances of vision and cessation of the menses. I simply exposed the mass and saw part of the tumor at the cut margin of the dura. I removed no part of the tumor, following the wish of Hofrat von Wagner, in whose clinic the patient was. In spite of that, the vision of the left eye improved from 6/60 to 6/18. The acuity of vision in the right eye was and remained normal, while the width of the visual field remained uninfluenced. This improvement in the left eye continued for about seven months, but the patient had to be operated upon a second time (which is recorded as Case VIII in the full report). The improvement to 6/18 vision now retrogressed to the original 6/60, and the patient requested a second operation. I removed a piece of the tumor about the size of a cherry. However, immediately after the operation the patient became unconscious and died a few hours later. Postmortem showed a large hypophysis tumor which had grown toward the third ventricle. Blood vessels were opened at the operation, the tumor tissue was covered with blood, and fluid blood entered the third ventricle. No other wound was found. Histological examination showed that the tumor was a vascular malignant adenoma.

"For the separation of the mucous membrane flaps, the usual short nasal speculum sufficed, but occasionally I used also the long-bladed nasal speculum (as is used in median rhinoscopy) in order to examine the ostia sphenoidalia. In working between the separated mucous membrane flaps there was a difficulty after removal of the anterior part of the septum. I lost my orientation as to which direction I must separate the mucous membrane further in order to come to the anterior walls of the sphenoidal cavity and not enter the lamina cribrosa. I found that by keeping near to the floor of the nose and loosening the mucous membrane from both sides of the vomer as far as the choanæ and also to that part of the vomer which forms the septum between the choanæ, this difficulty was lessened. After removal of this piece of bone I found upon introducing a probe between the flaps that the mucous membrane of the septum which lay in the region of the pharynx was yielding. Above that one felt a resistance which must be the anterior sphenoidal wall. Now I had the direction and the region where the mucous membrane must be pushed aside in order to reach the anterior walls of the sphenoidal cavity without coming into contact with the lamina cribrosa. The determination and opening of the hypophysis tumor offered no difficulty. . . . The chief factor in the endonasal submucous method is the anesthesia. All parts of the nose which may be touched by instruments during the operation must not only be cocainized, but also infiltrated with Schleich's solution; above all, the septum in its entire extent and the anterior walls of the sphenoidal cavity. I recommend also to infiltrate the posterior ends of the middle turbinates, since during the elevation of the mucous membrane from the anterior sphenoidal wall these parts may be pressed upon. If the anesthesia has been carefully done, the patient remains quiet during the operation and the physician can also rest easy in those cases in which the surgical attack lasts an unusually long time through unforeseen hindrances. Before opening the sphenoidal cavity, it is recommended to elevate the mucous membrane so that the ostia sphenoidalia become visible before undertaking the removal of the wall for the following reasons: (1) The bone is usually thinnest around the openings, and (2) through systematic removal of the sphenoidal walls toward the middle line the comparative situation of the two openings may be determined and any asymmetry and deviation of the sphenoidal septum may be seen. The removal of the sphenoidal septum is continued to the hypophysis tumor. If a portion of bone remains behind, it must be removed by a chisel before the operator can attack the real bone shell of the hypophysis tumor. Thereby the chiseling is made more difficult and one gets the impression of thick bone. I follow the example of Cushing, and because of the work of S. J. Crowe, in the use of urotropin after hypophysis operations. Crowe has demonstrated that after administration of urotropin formaldehyde appears in the cerebrospinal fluid and disinfects the same."

The instruments necessary for the hypophysis operation are as follows: (1) All those in common use for the submucous resection of the nasal septum according to the opinion of the operator. (2) The hooks and sphenoidal forceps used by Hajek. (3) A long elevator. (4) A septum forceps with blades 13 cm. long. (5) A chisel. (6) A large and small right-angled elevator. (7) A straight and an upward bent bone forceps. (8) A bone rongeur. (9) A knife for the dura. (10) Various sized curettes, one the size of a pea. (11) A syringe for infiltrating the anterior sphenoidal wall.

"After my experiences," says Hirsch, "it can be asserted that the endonasal submucous hypophysis operation not only compares very favorably with the extranasal surgical methods, but is superior in many respects. I am thinking here not only of Schloffer's method, but also of all other similar methods which have been described."

"Case XII.—In this case the endonasal hypophysis operation produced quite an extraordinary result, since the patient was a man sixty-nine years old, and a significant improvement of the visual power was obtained. The patient within eight months had lost his vision, excepting a small remnant. Before the operation he could count fingers with the right eye at four meters, the left eye perceived merely movements of the hand. After the operation, in which a soft cyst was opened and tumor tissue was removed, the patient obtained in the right eye a seeing power of 0.2. The left eye could now count fingers. The field of vision, which could be determined only in the right eye, is very limited, but in the nasal half is almost normal in extent. (The temporal half is still wanting.) On the left, the field of vision has returned in the upper nasal quadrant. I can assert that this result could have been obtained by no other method, since the patient could not have withstood a narcosis."

Finally, Hirsch reports one case with fatal issue, in which the wrong diagnosis had been made by the physician who submitted the case for operation. He says: "I operated upon another case in which the common signs of disturbances of vision, cessation of menses and *x*-ray picture showing excavation of the sella turcica led to the diagnosis of hypophysis tumor. The patient was advised because of this diagnosis to undergo operation. I made an opening about the size of a cent in the floor of the sella turcica and exposed and incised

the dura. The serous fluid came away. I believed at the time that a cyst was present. The serous fluid continued to come away, and a short time after the operation the patient became somnolent, and I began to suspect that the subarachnoidal space had been opened. The patient died two days later. At post-mortem a flattened but otherwise normal hypophysis was found. The diaphragma sellæ was markedly excavated in its anterior part adjacent to the sella floor. The floor of the third ventricle was adherent to the diaphragma. Under such anatomical conditions, by cutting into the dura the ventricle must necessarily be opened. It was probably a circumscribed hydrocephalus of the third ventricle. Meningitis was not present.

"Among the cases operated upon, the three forms of hypophysis tumor were encountered, causing the symptoms enumerated above: Acromegaly, degeneratio adiposogenitalis, and visual disturbances without striking general symptoms. All cases showed a significant improvement in symptoms (visual disturbances, acromegaly, and headache) after the operation. The fatal results which occurred after the operation would have also occurred after any other of the hitherto described methods and could not be avoided. The endonasal method is applicable to all cases in which the tumor forces the sella turcica forward toward the sphenoidal cavity. Good results are to be expected if the tumor for the most part develops only within the sella turcica or is of a cystic nature. In exceedingly great intracranial development of the tumor this operation, as well as all other methods, can be followed only by insignificant results. After what has been described above it is obvious that rhinology has won for itself in the endonasal hypophysis operation a new, interesting, and important field, and therefore it is now the business of nasal specialists, in selected cases, to take permanent possession of the newly won territory."

On September 15, 1911, Hirsch operated upon a thirteenth case of hypophysis tumor on account of visual disturbances. The visual disturbances have significantly improved.

On October 11 he operated on a fourteenth case in the same way on account of visual disturbances. This patient has also become quite well.

14 Central Park West.

ADDITIONAL NOTE UPON A SO-CALLED PARASITE OF YELLOW FEVER (SEIDELIN).

By ARISTIDES AGRAMONTE, A.B., M.D.,

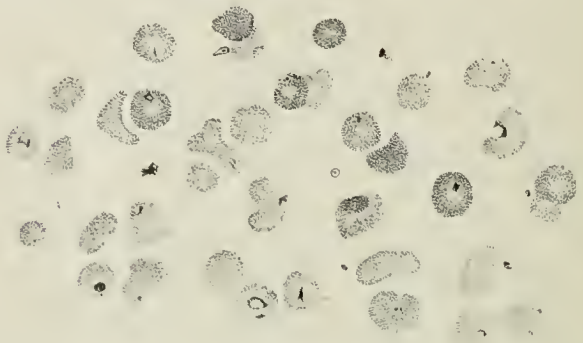
HAVANA, CUBA.

PROFESSOR OF BACTERIOLOGY AND EXPERIMENTAL PATHOLOGY, UNIVERSITY OF HAVANA; PRESIDENT, BOARD OF INFECTIOUS DISEASES; MEMBER OF THE NATIONAL BOARD OF HEALTH, CUBA.

Since writing my "Notes" referring to an article in the Yellow Fever Bureau Bulletin, No. 7 (Liverpool, England), in which a new "parasite" of yellow fever is offered for consideration, I have been engaged upon a study of blood films, secured from the various sources which shall be presently described, in a good proportion of which I have found bodies identical with those which have been accused of being the causative agents of yellow fever.

In my paper, above mentioned, I could do no more than offer a criticism of Dr. Seidelin's claims in a general way: I could not present any objective evidence against the specificity of his "organism," because my experience with the Giemsa stain, in the search for other parasites than malarial, was at that time extremely limited. Notwithstanding, I had had opportunities to appreciate its instability, the lack of uniformity in the results, even when apparently the same details of technique are carried out in the staining process, so that I did not hesitate to express as one of my conclusions, from the examination of the few preparations exhibited, that the bodies shown by Dr. Seidelin were likely to be "nuclear and proptoplasmic fragments."[1]

Subsequent investigation has demonstrated that my surmise was fundamentally correct and the so-called parasite of Seidelin can be reproduced, as far



Composite Drawing of Blood-findings Simulating Protozoon Bodies. Treated by the Giemsa Stain, Rapid and Slow Processes. X1800.

as cell fragments can be reproduced, with regard to size, coloring, and general appearance, in blood films obtained from other pathological conditions, in which the existence of yellow fever infection is absolutely untenable. Nor has the experience been restricted to my own researches for, entirely independent of my work, Dr. Cartaya in Las Animas Hospital Laboratory has found the identical "germs" in a case of human glanders, as well as in certain biliary infective processes; Dr. Guitéras, who has examined Cartaya's films, is also of the opinion that the bodies found there are the same as those shown to us by Seidelin in his preparations last winter.

It may be needless to say, perhaps, that these bodies cannot be demonstrated in a good number of blood specimens examined and only once have I seen a few in what may be called, from a hematological standpoint, a normal individual. My blood smears, with Seidelin's yellow fever parasite, were collected from the following sources:

One case of goitre, after operation attended by severe hemorrhage (collected by Dr. Lebredo at Hospital No. 1).

One case of measles; girl 15 years old; in the eruptive stage of the disease.

One case of mild biliary obstruction (gastroduodenitis?) at Las Animas Hospital.

Three cases of severe icterus, not possibly yellow fever (two at the Covadonga and one at the Benefica Sanatorium).

One case of uncinariasis, with the usual marked anemia.

One case convalescing from typhoid fever, who had suffered several intestinal hemorrhages during the attack (at the Covadonga Sanatorium).

One case of severe icterus (Weil's disease?) at the Benefica Sanatorium.

One case of urticaria; a woman, 32 years old, apparently otherwise normal.

On the other hand, it has been impossible to find these unusual bodies in preparations made from 27

normal individuals (18 men, 7 women, and 2 children) in those from grippe (3 cases), chronic dysentery (1 case), infectious icterus (2 cases), typhoid fever at various stages (3 cases), in any of four blood smears from a case of yellow fever at Bahia (Brazil). These specimens were collected at the fourth day of the disease. I have had no opportunity to examine other blood films from yellow fever, still the experience obtained otherwise inclines me to the opinion that the elements described by Seidelin may, indeed, be frequently seen in that disease; but from this, to associating them in any capacity with the etiological factors concerned in yellow fever, there is such a great distance, that it may not be easily bridged over.

When once we realize that these bodies are nothing but nuclear and protoplasmic fragments, chromatoid and basophilic elements, and thus integral parts of the blood itself, we can well understand the reason for many of the points so faithfully presented in Dr. Seidelin's description of his supposed parasites. One of these, and because of which I was averse to accord to them the rôle of causative agents of the disease, was their dissimilarity of size and form even when found in the same drop of blood; the fact that no two of these bodies were exactly alike, except perhaps in the case of the small chromatic points, the so-called "marginal dots" (Jolly bodies?), which Theiler has turned into his *anaplasma* of cattle and which sometimes appear with the selective stains even in normal blood. But the bodies that apparently contained a certain amount of protoplasm, which Seidelin considers as the most typical *paraplasmata*, failed in that uniformity of contour and proportional contents which we are accustomed to see in protozoan bodies. Among the "parasites" drawn by Seidelin there is one, however, the counterpart of which I have found twice; it consists of a rather square bit of basophilic substance, about two microns in diameter, the third part of which is occupied by a more or less crescentic chromatoid nucleus, simulating the blepharoplast of a protozoon.

Another fact which is also explained is why these elements have been seen by Seidelin in yellow fever blood, obtained rather late in the disease, after the fourth day and not during the first three days; the reason, to my mind, is that the hematopoiëtic activities of the individual are then most pronounced, after actual hemorrhages, hemolytic or other blood-destroying processes have been at work and the blood-forming powers are stimulated to produce, as is well known, new blood with its fair amount of nucleated erythrocytes, normoblasts, and the corresponding proportion of white blood cells; it is then we find an unusual quantity of nuclear elements which on staining give the chromatin reaction in a manner more or less pronounced, according, as I suggest above, to the specific details of technique employed, not only with the Giemsa, which is one of the simplest used and hence the preferred in protozoological investigations, but as well with all the various other modifications of the Romanowsky type of stains.

Yet another of Seidelin's findings which I have been enabled to corroborate is the scarcity of these bodies in whichever blood specimen they may occur. In some slides barely two or three may be seen after hours of painstaking search, and this is particularly so with regard to the larger and more protozoon-like fragments, so that a collection of half a hundred "parasites" represents the work of as many hours. This infrequency in the blood is readily explicable when we think of the eventual origin of their existence and the very fact of their insignificance.

I believe with Shilling (Torgau) that many investigators in the field of Tropical Medicine have mistaken these elements as the causative agents of the particular disease which they may have been studying at the time. He mentions several who may have committed this error, but with regard to Seidelin he specifically says:[2] "It is entirely inadmissible that one may declare a case of yellow fever, for the only fact that it presents those 'parasites,' (Seidelin)."

And in a footnote to this page, he adds: "The histories themselves, presented by Seidelin, make their etiological nature improbable. The diagnosis based only upon the finding of these 'parasites' would be too far fetched."

In this excellent work of Shilling's we find that many of his drawings of these blood elements are as much like Seidelin's "parasites" as any two fragments of anything that cannot be mathematically broken up can be.

A very interesting contribution to the elucidation of this subject may be read with benefit by researchers in the Tropics, where blood conditions, both in the native and the European as well, are usually far from normal as we understand them; it is found in the Fourth Report of the Wellcome Laboratory (Khartoum, Egypt) from the pen of Dr. Andrew Balfour. The interpretation of microscopic findings must be kept well safeguarded from the personal equation: else one is liable to become the victim of some of the many fallacies pointed out by that eminent hematologist.[3]

My work has been necessarily restricted to human blood, the time at my disposal not allowing the extension of research beyond the object in view, which was mainly to corroborate or disprove the exclusive existence of those bodies in the blood of yellow fever cases. Similar findings have been announced in other mammalian, as well as in fowl and reptilian blood, which no doubt are of interest to students of hematology; most of them, if not all, may be found reported in the *Folia hematologica* of Pappenheim.

During the work entailed in the preparation of this "Additional Note" I have demonstrated, in a manner quite satisfactory to my colleagues here and to myself, that the "parasites" of yellow fever said to have been contained in the stained slides shown by Dr. Seidelin cannot be accepted as such, from the fact that evidently blood-platelets, chromatin residues, desintegrating cell remnants, nuclear and protoplasmic fragments often present the same hue and outline when treated by the selective stains and principally by the Giemsa reagent, and unless Dr. Seidelin can bring forth other and more substantial proofs of his contention, we must reverently but decidedly lay his "parasite" in the grave which holds so many disappointments that have attended, heretofore, the researches of discoverers, certainly as earnest and enthusiastic.

A composite drawing of the bodies demonstrated accompanies this writing.

BULLOUS DERMATITIS FOLLOWING VACCINATION, WITH A REPORT OF A CASE.*

By J. L. KIRBY-SMITH, M.D.,

JACKSONVILLE, FLA.

In recent years quite a few cases of bullous dermatitis have been reported in the current medical literature as having followed vaccination. Among the well known dermatologists who have observed this condition, and have brought up the question of vaccina being the causative agent in the eruption, are: Bowen of Boston who reported in the *Journal of Cutaneous Diseases* in 1901: "Six cases of billous eruption resembling herpetiform dermatitis following vaccination, in children between the ages of five and ten, and appearing within from one to four weeks after vaccination, and lasting from months to years; Dyer of New Orleans also makes a report of the same condition at an earlier date (1897) in the *New Orleans Medical and Surgical Journal;* Pusey of Chicago, previous to Dyer, reported a similar condition in the May (1893) number of the *Tri-State Medical Journal;* Stelwagon in the *Journal of American Medical Association,* February 22, 1902, in an article, "Vaccinal Eruptions," reports bullous dermatitis following vaccination; others who have reported cases are Howe of Boston, who reported a series of ten cases, and Sequiera in 1902 showed before the London Derma-

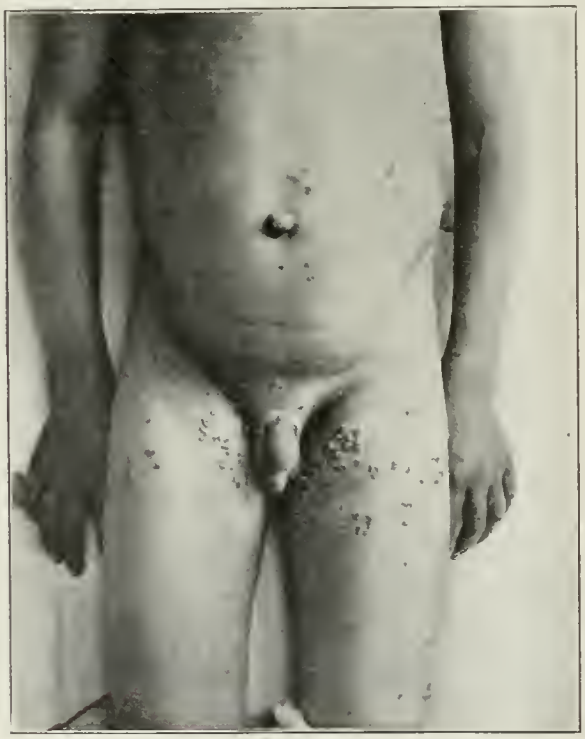

Fig. 1.

tological Society a case of pemphigus following vaccination. Schamberg in his latest treatise on the "Eruptive Fevers" reviews the subject of vaccina-

*Read before the Duval County Medical Society, March 5, 1912.

tion as being the causative factor in certain bullous eruptions; he states that, "In relatively rare instances vesicobullous eruptions, variously designated as acute pemphigus, bullous dermatitis, herpetiform dermatitis (Duhring's disease) have followed

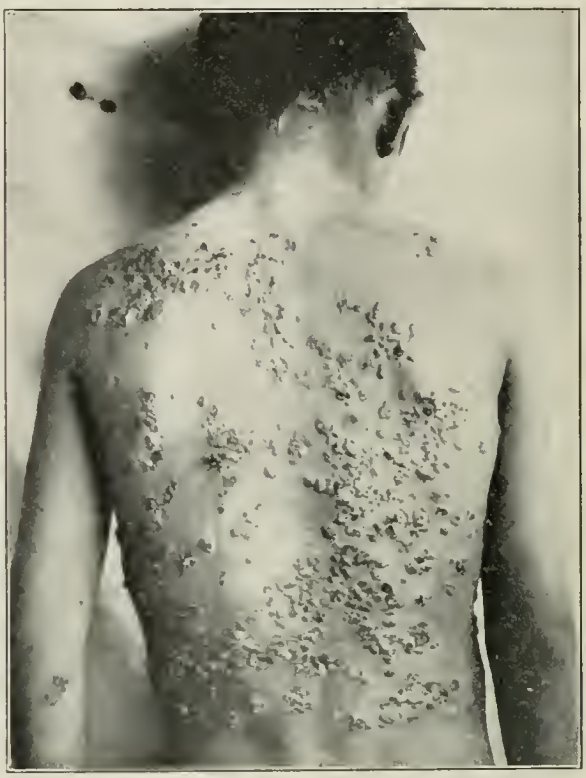

Fig. 2.

vaccination. While we have found no positive proof of a causative relationship between vaccina and these eruptions, they have been reported by careful observers in a sufficient number of instances to warrant the assumption that the antecedent vaccination has been of some etiological moment." To quote from Stelwagon in his treatise on "Diseases of the Skin," under the head of "Etiology of Herpetiform Dermatitis," we find, "That some septic or otherwise toxic agent is sometimes responsible for herpetiform dermatitis (or at least a similar or allied condition showing often a combination of the symptomatology of erythema multiform, herpes, pemphigus, and resembling herpetiform dermatitis), seems shown by the occasional examples following vaccination, as observed by Dyer, Pusey, Bowen, myself, and others." Howe, in his report of bullous eruptions following vaccination, was inclined to attribute the eruption to the infectious material introduced at the time of, or after, vaccination. The cases occurred at a time when smallpox was prevalent in epidemic form, and when thousands of vaccinations were being performed.

Case History.—Roy Crozier, referred by Dr. John E. Boyd of Jacksonville, May, 1910; age as given nine; family history: father and mother both living, four children (boys) who have always been strong and healthy; in fact, the whole family are apparently in good health; there is no history of any skin disease in the past. The patient is the eldest child, has had the best of health; whooping cough when an infant is the only disease of childhood; one year ago was treate l for "hook-worm," report from the State Board of Health Laboratory had previously shown the presence of the ova of Uncinaria:

later examination showed the stools free from the parasite.

According to the statements of the mother, the child was vaccinated on the arm one year ago, by the family physician; the vaccination was successful; ten days after the inoculation a number of clear water blisters made their appearance on the arm in the neighborhood of the vaccine pustule; a few days later similar lesions appeared on the body, and then on the face. From this time until seen by me, in May, 1910, the patient has never been entirely free of the eruption. The mother states that "as soon as one crop of blisters would dry up and the crusting separate, the disease appearing to be about over with, other crops would make their appearance over night; during all this time the boy was in good health; he complained of intense itching at times, especially at the time of occurrence of new lesions." Until recently the disease has not prevented him from taking part in the life of chil-

Fig. 3.

dren. When first seen in May, 1910, there were a number of groups of vesicobullous and vesicopustular lesions on the body and extremities (as shown in Fig. 1), especially around the thighs and genital region, and a few scattered lesions on the face and neck; though the predominating lesions were vesicular, some were pustular; these no doubt were secondary, due to infection from scratching; others were ruptured and a crusting resulted. There was some light colored pigmentation present and slight superficial scarring from previous lesions; there was a decided tendency toward grouping; this is shown in Fig. 1. Itching at times was complained of as intense; with these characteristic symptoms present, a diagnosis of herpetiform dermatitis was made. Acute pemphigus and bullous impetigo were both considered in a differential diagnosis, but the latter was excluded after considering the history of the frequent recurrences over such a long period of time, and definitely so by the absence of pyogenic bacteria in the serum from the vesicles and bullæ. Acute pemphigus was excluded by the decided grouping of the lesions and the presence of the intense itching. Later, however, the recurrences of the eruption, as shown in Figs. 2 and 3, made this diagnosis appear to be more correct than that of herpetiform dermatitis. A complete physical examination revealed nothing abnormal; a number of urinalyses were made, the only thing of interest found being the constant presence of indican. Examination of the blood showed 7 per cent. eosinophilia. Mention is here made of the long prepuce of the patient, which was found to be adherent to the glans, and I think that by circumcision the occurrence of the eruption may be controlled, as some cases of herpetiform dermatitis in children have been cured by this procedure (Stelwagon). Treatment as a whole has been very unsatisfactory. The mother has refused to allow circumcision, internal medication has had very little effect, full doses of arsenic in Fowler's solution were tried, also quinine and mercury; the best results obtained have been from injections of 2 grains of sodium cacodylate twice a week over a period of six weeks. Last summer the patient remained free from the disease for two months. This is the longest period he has been free of the lesions since the first occurrence eighteen months ago. The present eruption is the most severe (see Figs. 1 and 2).

Circumcision was performed by Dr. W. P. Dey of Jacksonville, on March 10. The prepuce was found to be firmly adherent to the glans penis; had to be dissected free. At the present time, May 28, the patient has been free from the eruption five weeks.

A MARKED CASE OF FACIAL ASYMMETRY OCCURRING IN A CASE OF SCROFULODERMA.*

By M. ZIGLER, M.D.,

NEW YORK,

INSTRUCTOR IN GENITOURINARY SURGERY IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CHIEF OF THE GENITOURINARY CLINIC OF LEBANON HOSPITAL; ASSISTANT DERMATOLOGIST OF LEBANON HOSPITAL DISPENSARY.

Tillie G., age twelve years, Russian parentage. The father and mother are apparently in good health. Two years ago the patient had an illness which lasted several months and was characterized by fever, chills, and cough. Six months ago she noticed an eruption on her chest and right buttock. These lesions have persisted ever since.

Status Præsens.—Patient came to the skin department of Lebanon Hospital (Dr. William S. Gottheil's service) about April 15, 1911. Physical examination showed the following: Child appears of normal mentality, even bright. On inspection of head and face one is immediately impressed with the marked differences between the right and left sides of her face, the former being very much more prominent and protruding considerably forward, while the latter appears to recede. She turns her head to the right as her natural posture. In addition, her features are all in an oblique plane, slanting at an angle of 15 degrees from the right side, downward to the left, the right eye and ear being on a higher plane than the left. The right ala nasi and the right side of her mouth are also on a higher plane than the left. No facial paralysis present. Spinal column shows a lateral curvature.

*Case reported at a meeting of the Lebanon Alumni Society.

On palpation of the right side of the face considerable thickening of malar and superior maxillary bones is found, especially marked over the zygomatic arch.

Radiograph by Dr. I. J. Landsman shows the right face is higher than the left, an elevation of about 15 degrees. The right nostril is higher than the left, the right eyeball correspondingly higher. The right antrum of Highmore is smaller than the left. The maxillary bone on right side is somewhat more dense. Fundus examination by Dr. C. Barnert gave negative findings.

Physical examination of the chest shows at the upper part of the sternum a heart-shaped lesion covered with crusts, which seven days ago was covered with hypertrophic granulations. On closer examination we find this large lesion is made up of four isolated lesions which have coalesced to form one. Toward the upper and left extremity of the

From a photograph showing the facial asymmetry and the chest lesion.

right buttock near the intergluteal fold, there is situated an irregularly oval shaped ulceration with a somewhat depressed center, covered with grayish yellow crusts, oozing a thin serum on removal of the crusts. This lesion, as well as the one on the chest, is not painful and is non-inflammatory in character. The pathological report was that there was a negative Wassermann reaction, and a positive von Pirquet.

Treatment.—Patient received balsam Peru dressings. Later several applications of solid carbon dioxide, together with pill creosote internally, under which medications the lesions rapidly healed.*

This case is reported because of the rarity of such marked facial asymmetry and also because of its occurrence in a scrofulous patient.

*Since this article has been written the chest lesions have reappeared.

1097 Forest Avenue.

A CASE OF SARCOMA OF THE ORBIT.

By DAVID WEBSTER, M.D.,

NEW YORK,

SURGEON MANHATTAN EYE, EAR AND THROAT HOSPITAL.

Edward B., colored porter, age 34, married, came to me February 11, 1909, to consult me in regard to lumps under the skin of the lids of his right eye. He said that he had caught cold about two months previously and his right eye started to run water which scalded the skin a little. He noticed a kernel under his chin and another in front of his right ear, and he "rubbed it up into the eye instead of rubbing it down," as he should have done. He denied venereal disease.

R. V. $=\frac{20}{20}$ L. V. $=\frac{20}{40}$. Media and fundus normal. The eyeball was pressed forward and toward the temporal side of the orbit. Upon palpation a nodular tumor could be felt above and below the inner canthus. On March 3 I removed the portion of the growth that presented beneath the upper orbital margin, but could not reach the whole mass without too much traumatism. Five days later, at my request, Dr. Edgar S. Thomson performed the Krönlein operation and removed the remainder of the tumor piecemeal. It was found to extend far back into the orbit. The tumor was examined by Dr. Edward L. Oatman, one of the pathologists of the Manhattan Eye, Ear, and Throat Hospital, who said it was a round-celled sarcoma.

There was very little inflammatory reaction, the wound healing by primary union.

May 2. No exophthalmos; the eyeball has resumed its normal position. The eye does not see as well at short range, and there has been diplopia on looking down since the operation. R. V. $=\frac{20}{20}$. L. V. $=\frac{20}{30}$. Eyes move equally in all directions except in looking far down when the right eye lags behind, and there is diplopia. Pupils of equal size and react normally to light and to accommodative effort. The scar of the Krönlein operation is inconspicuous.

May 18. Some edema of the lower lid, and some thickening can be felt at the lower orbital edge. Boric acid wash prescribed.

July 6. There is a stye at the nasal end of the right upper lid, and there is still some diplopia on looking down.

October 18. The lids are normal and nothing abnormal is to be felt in the orbit or on the orbital border. Diplopia still persists on looking down.

March 31, 1910. Comes with an eyelash protruding from his right punctum which causes a good deal of irritation. The eyelash was extracted.

October 30, 1911. Patient comes to the office in a healthy condition. He does not see double on looking down or in any other direction. The scar of the operation is noticeable only on close inspection.

It will be observed that this tumor extending far back toward the apex of the orbit, and with nodular prolongations above and below the eyeball, was removed without injury to the optic nerve,

and without permanent impairment of the functions of any of the ocular muscles. It is also worthy of note that there was no return of the growth more than two and a half years after its removal, though it was of a malignant character.

308 Madison Avenue.

CELLULITIS OF THE ORBIT.*

By F. P. HOOVER, M.D.,

JACKSONVILLE, FLA.

Orbital cellulitis is a disease one does not meet with every day in general practice, and even the specialist rarely has a case of the kind under his care. Some of these cases are very often confused with other affections that are similar in appearance and manifestations, in fact, not infrequently is a diagnosis made of exophthalmos instead of cellulitis, and only recently such a case presented itself to me.

A man, about forty-five years old, saw me two years ago. At that time his left eye was somewhat bulging and prominent, but as he called on me regarding another matter no mention was made of the eye. When last in my office he recapitulated to me his experience and all he had been through, with his "formerly bulging eye," as he expressed it, during the interval since we last met, and it was this experience that suggested this article. He said in one city two specialists had an animated and heated argument as to the diagnosis of his case. One said exophthalmos; the second said the trouble was the result of a tumor. Other ophthalmologists consulted elsewhere in other cities said the swelling and protrusion of the eye were from various causes; only two pronounced the disease cellulitis, and one of them would not do so positively. The one that diagnosed cellulitis had operated upon him. The operation was successfully performed and the result was most satisfactory. To all appearances when I saw the eye it was like its fellow; there was no difference in the movement of the lids or muscles, and the eye, seemingly, was normal.

Just why there should be so much uncertainty pertaining to these conditions can be better understood by considering the differential symptoms of each disease cellulitis simulates. Pulsating tumors of the orbit are hard to diagnose and it is more by exclusion of other forms of disease than by positive indications that we can reach a satisfactory diagnosis. A pulsating tumor may be the consequence of a fracture at the base of the skull involving the internal carotid in the cavernous sinus. Compression of the carotid generally causes a marked diminution of the bruit, and sometimes it is accompanied by fullness and pain in the head. Bulging of the eyeball has occurred from a diffused aneurysm, which has formed in the cellular tissue of the orbit as a result of some injury or from disease or rupture of a vessel. Here there is pulsation of the eyeball, the arterial souffle heard may be stopped if the eyeball is very gently pressed back into the socket, and then pulsation of the globe ceases; but if the pressure is removed the eyeball will return to its former position and pulsation is renewed. With a stethoscope placed above the supraorbital ridge, when there is aneurysm of the ophthalmic artery, the arterial bruit is distinctly audible, accompanying the pulsations of the eyeball, which is protruded. When a tumor forms in the orbital cellular tissue the eyeball will gradually protrude *pari passu* with the growth of the tumor; this is so with erectile tumors which grow slowly. Cancer of the orbit will cause a similar condition, only more rapid in its development; then, too, the bones will likely be involved, but not so necessarily. Cysts of the orbit produce bulging of the eye, and only by use of an exploring needle can one *positively* determine whether there exists a tumor or cyst. Bony growths of the orbit will cause protrusion of the eyeball, also abscess of the antrum, which may force the interior wall of the orbit forward. In Basedow's disease (exophthalmos) both eyes protrude, but *occasionally* only one eye will do so. Pain is an accompanying symptom of cellulitis of the orbit; it is increased on pressure, and it is of an aching or neuralgic character; also there is protrusion of the eyeball with swelling of the lids; there may be also some impairmen of the vision. The condition may be the result of erysipelas, periostitis, traumatism, or septicemia. The patient above referred to had never at any time symptoms indicative of cellulitis of the orbit beyond protrusion of the eyeball and swelling of the lids; he had no pain or discomfort except inability to close the lids of his eye; light of course caused him annoyance. He was well nourished and daily attended to his business, being a traveling man.

Mutual Life Building.

*Read at the annual meeting of the Florida State Medical Society, at Tampa, May 8-10, 1912.

The Wassermann Reaction in the Blood of the Umbilical Cord, the Maternal Blood, and the Blood of the Child After Birth.—A. Serra and A. Gentili have made tests of the Wassermann reaction in pregnant women; they also tested the blood of the fetus, the blood of the umbilical vein, the cerebrospinal fluid of the fetus and the placenta. Tests were made immediately after labor and in the puerperium, and the results were compared in women who were normal, who were suspected of syphilis, and who were evidently syphilitic. Some had been treated and others had not. There were 23 syphilitic women out of 110; in these the Wassermann reaction was positive in 17, either in the blood of the mother or of the umbilical cord. It was positive in all the mothers who were in the florid period of syphilis; according as the interval from the beginning of the secondary stage was longer the positiveness of the reaction diminished. Mercurial treatment had the same effect as in syphilis outside pregnancy. The Wassermann reaction is also positive in eclampsia and in malaria, while it is always absent in normal pregnancy and pregnancy accompanied by complications other than eclampsia and malaria. In the syphilitic fetus it was positive 50 to 120 days before any manifestations of the disease were found. It is at first only partial, gradually increasing in positiveness; it may be absent when there has been energetic mercurial treatment. The placenta of the woman who has given birth to a syphilitic fetus may be entirely normal; in the macerated fetus the villi are flattened and the intervillous spaces are narrowed; there are also vascular lesions, but no formative process in the epithelia covering the villi; the membranes showed no changes; organisms were found in the fetal side of the placenta. In women who are not syphilitic macerated fetuses may be found showing that death and maceration may arise from other causes. The reaction is positive in the cerebrospinal fluid of a fetus that has died of syphilis, and in macerated fetuses when the blood of the mother shows no evidence of syphilis.—*Annali di Obstetrica a Ginecologia.*

RECENT ADVANCES IN THE STUDY OF SCARLET FEVER.

BECAUSE of its obscure etiology and of the seriousness of its complications and sequelæ, scarlet fever has been the subject of a great number of studies, many, unfortunately, without markedly satisfactory results. here has been a rather persistent belief that to the streptococcus or to one of its strains should be assigned either the cause of the disease or at least the determining factor in the development of its many complications. This organism is known to be present in the throats and in the pus from suppurative complications, also it is known to grow less vigorously in tropical climates, where scarlet fever is said to be less serious and to be attended with complications less frequently. The belief, however, has remained without proof, and Klimenko (*Centralblatt für Bakt.*, Bd. 65, p. 45) has recently conducted an exhaustive bacteriological study of 523 cases of scarlet fever in an endeavor to determine the relationship of the organism to the disease.

Blood taken from the patients was cultured on several kinds of media. At autopsy on 48 of the fatal cases blood was taken both from the heart and from a peripheral vein for this purpose. His results are important. In only 11 cases (2.1 per cent.) was the streptococcus recovered from the blood during life, these cases being all of the severe or complicated variety. The presence of the organism seemed to have no relation to the development of kidney, heart, or joint complications, which were present in 94 cases. He found it in the cultures of blood from either the heart or periphereal vein in 31 of his 48 autopsies, but points out that other investigators have found it in post-mortem blood cultures from patients dead of a large number of diseases, and that in these instances the organism represents probably a post-mortem invasion. He concludes that the streptococcus is never present in the blood in early stages of scarlet fever and that it bears no causal relation to the development of the disease itself or of its complications. When the streptococcus is added, he declares, the picture becomes that of "septicopyemia."

In another direction new observations have been made. Döhle (*Centralblatt für Bakt.*, Bd. 61, p. 63) first described certain bodies found in the polymorphonuclear leucocytes in scarlet fever, to which he gives the name "leucocytic inclusion bodies" (Leukocyteneinschlüsse). These bodies are round or oval or even rod shaped, and vary greatly in size. They stain readily with all the usual blood stains, taking the basic dye. They do not show any chromatin staining. Döhle found them regularly in the blood of thirty patients with scarlet fever, and but rarely in other conditions. He describes them as being very different in appearance from the inclusions found in cells in the lymph nodes and kidneys by Bernhardt and Höfer, and is inclined to think that they should be of a certain diagnostic value. His results were confirmed by several other investigators. In a later communication (*ibid*, Bd. 65, p. 57) he reports the finding of spirochætæ in the leucocytes from two cases of scarlet fever, and expresses the opinion that the "inclusion bodies" may represent portions of these spirochætæ which in turn may very possibly be the cause of scarlet fever. He has been unable to infect white mice, rabbits, or pigs with these bodies by injecting into them blood from scarlet fever patients.

In Philadelphia, Kolmer has investigated 216 cases of scarlet fever and over 150 cases of other diseases with the idea of estimating the diagnostic value of the "inclusion bodies." He reports (*Am. Jour. Dis. of Children*, iv., p. 1.) them present in 94 per cent. of 49 cases of scarlet fever examined during the first three days after the onset, but diminishing rapidly after that time and rarely being present after the ninth day. In 22 cases of diphtheria they were present in 42 per cent. during the first three days, and but seldom after that time. In 11 cases of erysipelas they were present in 62 per cent. examined at various times in the disease. They were absent in 30 cases of serum sickness presenting an urticarial rash and in 13 cases with scarlatiniform rash. Also they were not found in many other diseases in which the blood was examined.

Kolmer concludes: "The diagnostic value of these 'bodies' is necessarily limited. In serum sickness with a scarlatiniform rash their absence excludes scarlet fever with a fair degree of accuracy. Their presence in this condition, however, may not be due to scarlet fever, but to the primary attack of diphtheria. They have, therefore, a negative value. An examination of the blood for these 'bodies,' however, is very simple and possesses value in aiding a differential diagnosis between scarlet fever, rötheln, measles, and gastrointestinal rashes."

CAFFEINE AND EFFICIENCY.

FOR a long time the properties of stimulating mental processes, of delaying the onset of fatigue, and of inducing wakefulness, have been generally recognized in caffeine and in beverages containing it. In addition to this knowledge the concepts of coffee and "nervousness" have been closely associated in the minds of the laity, even though the consumption of coffee has not materially diminished as the result of this knowledge. The good and bad effects of coffee or tea, a cup of which contains from one and a half to two and a half grains of caffeine, are well known, and little in the way of experimental proof has been sought in confirmation of this knowledge.

In a monograph on this subject, H. L. Hollingworth* presents the results of a careful psychological study which he conducted for forty days on a series of sixteen individuals, mostly students, whose ages ranged between nineteen and thirty-nine years. These were given at different intervals measured doses of caffeine mixed with sugar of milk and administered in capsules. In the subjects who were used as controls only sugar of milk was administered in this way. None of the subjects knew at any time whether he was getting caffeine or not. In this manner the effects of expectation, suggestion, or enthusiasm in producing favorable or unfavorable results were eliminated from the experiments. The tests employed were those that are well known to psychologists as means of gauging mental efficiency. One of these was the color-naming test, by means of which the speed of association of ideas with words could be readily measured. The subject was required to name one hundred colored squares arranged in random order in ten lines on a white cardboard. The score was recorded by an assistant who noted in fifths of a second the time taken to name all the colors correctly. Another test was that of "naming opposites" or words with a meaning opposite to that of words typewritten on a cardboard, in which test the time taken in this mental process was also recorded. Other experiments were employed to test discrimination, attention, and judgment. In the "steadiness" test there was measured the ability of an individual to hold with his outstretched arm a metal rod passing through a hole in a brass plate in such manner that there would be as few contacts as possible between the rod and the side of the opening. In this test all movements beyond the slightest tremor were recorded by the apparatus. In the "tapping" test the time taken to execute by means of a metal rod as rapidly as possible four hundred taps on a metal base was recorded. The power of coordination was measured by having the subject insert successively and as rapidly as possible a metal rod into each of three holes arranged in the form of an equilateral triangle on a brass plate. This experiment furnished a combined test of steadiness, speed, and coordination.

In conducting the various tests the factors of fatigue, practice, time of the day, influence of meals, and the health and subjective sensations of the individual experimented upon were all taken into account. The results obtained with the tapping test were as follows: The typical motor caffeine effect was one of stimulation, sometimes preceded by a brief and slight initial retardation. The magnitude of the stimulation which began from forty-five to ninety minutes after the administration, varied directly with the size of the dose, up to six grains, and was relatively slight when the caffeine was taken in the morning. The effect persisted for from one to two hours for doses of one to three grains, and as long as four and a half hours for doses of six grains. There was no secondary or after effect shown within the seventy-two hours over which the intensive doses were traced.

The steadiness test showed a slight nervousness following the administration of one to four grains of caffeine, and a pronounced unsteadiess following the administration of six grains. This unsteadiness was greater if the caffeine was taken in the afternoon, and especially if unaccompanied by food. Small amounts of caffeine stimulated the power of coordination, while larger amounts caused a retardation of the latter. The speed of performance in typewriting was quickened by small doses of caffeine (one to three grains) and retarded by larger doses (four to six grains). The quality of the performance as measured by the number of errors, was superior for the whole range of caffeine doses when compared to the quality yielded on the control days. In the color-naming test there was an indication of stimulation for the whole range of doses employed. Stimulation was also observed in the cases of the "opposites" test; the magnitude of the caffeine influence varying inversely with the body weight, being greater when the caffeine was taken along with the midday meal, but being greatest when taken in the middle of the afternoon without food.

In studying the effect of caffeine on discrimination and choice reaction times it was noted in contrast to the results obtained with the tests above recorded, that small amounts of caffeine tended to produce retardation in discrimination time, and that this retardation was accompanied by a greater number of false reactions. This discrepancy is explained by Hollingworth as being probably due to the greater voluntary caution in the attempt to eliminate the false reactions. In this test it is stated that simulation does not make for efficiency except after long practice.

Of particular interest are the observations recorded with reference to the effect of this drug on sleep. Doses of from one to four grains had no appreciable sleep-disturbing effects except in a few individual cases. Doses of six grains markedly impaired sleep, although a few individuals did not experience this effect, which was greatest when the drug was taken on an empty stomach and on successive days; it did not depend on the age, sex, or previous caffeine habits of the individual, but varied inversely with the increase in body weight. As regards the effect of caffeine on the general health of the subject it was noted that irritability and headache followed the use of the larger doses. The two principal factors which seemed to modify the degree of caffeine influence were body weight and the presence of food in the stomach at the time of the administration.

Hollingworth in the interpretation of the results of his experiments points out that these show the complete absence of any traces of secondary depression. This conclusion is hardly justified. It would be logically more correct to state that the experiments do not reveal any evidence of secondary depression excepting in the tests of steadiness and discrimination. Mental efficiency, at any rate, considered as a whole, cannot be measured by any

*The Influence of Caffeine on Mental and Motor Efficiency", by H. L. Hollingworth, Ph.D., Instructor in Psychology, Barnard College, Columbia University. "Columbia Contributions to Philosophy and Psychology", Vol. XX, No. 4. New York: The Science Press, 1912.

one test or by a number of tests considered separately. The author states that no one knows "whether this increased capacity comes from a new supply of energy introduced or rendered available by the drug action, or whether energy already available comes to be employed more effectively, or whether the inhibition of secondary afferent impulses is eliminated, or whether fatigue sensations are weakened and the individual's standard of performance is thereby raised." Certainly no new supply of energy is introduced by caffeine. Nor is it probable that the energy already available is rendered more effective. Moreover, the *sensations* of fatigue can have no effect upon the output of energy. The true interpretation of the stimulating effect of caffeine as of that produced by any other drug would appear to be that under ordinary conditions the cells do not utilize their full store of energy; there is a certain amount held in reserve for unusual occasions and contingencies. The action of the drug tends to bring out this reserve supply; the result is stimulation, which, when frequently repeated, results in exhaustion. Hollingworth states that caffeine may be contrasted with strychnine, which causes a secondary reaction of depression. This contrast is only apparent. Depression is probably present in the case of caffeine, but is latent; and in this respect caffeine differs from none of the other alkaloidal drugs, in which depression always follows stimulation, though to a varying degree and at a varying interval of time.

As another curious example of *non sequitur* may be cited the following statement by Hollingworth: "The widespread consumption of caffeine beverages under circumstances in which and by individuals for whom the use of other drugs is stringently prohibited or decried seems to be justified by the results of experiment." The author admits that the results of his investigations bear only on the immediate effects of caffeine on performance; and that they do not apply to the continuous use of the drug, nor to the physiological or neurological effect of caffeine. But none of these effects can be ignored in making any statement as to the effect of caffeine on efficiency, which presupposes the healthy operation of many mental and physical processes.

Of related interest is the experimental study on the toxicity of caffeine conducted on different species of animals by W. Salant and J. B. Rieger (U. S. Department of Agriculture, Bureau of Chemistry, Bulletin No. 148, April 4, 1912). These observers found that the toxicity of caffeine varies in different animals, and that it is less in the young than in the adult. The presence of pathological conditions increases the toxicity of the drug. It is this last fact that should be taken seriously into account in all investigations that are undertaken with reference to the influence of caffeine on human efficiency.

THE SMOKE PROBLEM.

The deleterious effects of smoke from the burning of soft coal have not heretofore been very conclusively determined, though thousands have worked upon this important subject. However, "a smoke house"—that is, a laboratory so constructed that it is possible, by varying conditions, to get any kind of coal smoke for physical and chemical study—has been constructed at the Department of Industrial Research of the University of Pittsburgh[1]; and here it is hoped that scientific and fruitful work will be forthcoming.

Investigations are now making as to the amount of annoyance or suffering by reason of excessive smoke that is sustained in dwellings, hotels, hospitals, picture galleries, museums, office buildings, banks, libraries, and shops; as to the detrimental effect of smoke upon civic esthetics, upon the "city beautiful"; as to the meteorological aspects of the smoke problem; as to the effect of smoke upon plants and upon human health. The botanical side of this question well merits a word. While the relation of plants to smelter fumes and so forth has received much attention, little consideration has been given to carbon with the accompanying tar-contaminating phenol and other like compounds. Benner has found 44 per cent. tar in samples of soot examined. He wisely notes that such carbon smoke might have a very injurious effect on vegetation, especially in the spring, when the new leaves and tender shoots are the more readily affected by the toxic action of the soot and accompanying substances.

The relation of smoke to human health has probably thus far not been studied with any great definiteness. Does the inhaled soot predispose to tuberculosis is a question that has been variously answered. Pittsburgh, it is averred, does not have as much consumption as other cities similarly located where there is much less smoke; and there is more consumption in the better residence portions of Pittsburgh, where there is less smoke and dirt, than in the more congested districts, where smoke abounds. On the other hand "catarrh," pneumonia, and other "bad air" diseases are very prevalent, presumably by reason of the irritation of the smoke particles. It is furthermore said that because of swallowed mucus gastric ailments are indirectly attributable to smoke. And the ophthalmologist is busiest in Pittsburgh after a heavy fog accompanied by smoke. It is hoped by Benner that the study of the medical, with other phases of the smoke evil will be scientifically conducted in his laboratory; physicians will certainly be interested in the work and will no doubt find great gratification in its outcome.

BACTERIA CARRIERS.

There is a certain tendency, which comes to the fore under special conditions, to refuse to take the germ carrier with sufficient seriousness. In the sanitary administration of towns, institutions, and schools where examinations for the detection of carriers involve much time and expense, to say nothing of other obvious stumbling blocks, it is only human for authorities to fall back on the assertion that certain disease germs are ubiquitous, and that even if they should be found in certain individuals they may be non-virulent. Before the term "carrier" was used it was often stated that

[1]Benner, R. C.: "Research on the Smoke Problems," *Science*, June 28, 1912.

bacteria could be present in the healthy and do no harm either to the bearer or to others; and that the actual culpable disease-factor was something unknown—the *genus epidemicus*, in virtue of which the inoffensive germ took on virulence, to part with it again when the epidemic ceased. With a view of correcting some of these impressions, Sobernheim, at a recent meeting of the Berlin Medical Society (*Deutsche medizinische Wochenschrift*, July 11), made a distinction between the accidental carrier who himself is naturally immune, *pro tempore*, and the host who having recovered from the disease still carries with him germs of the stock which first infected him. Both these individuals are nearly as dangerous as a subject in the midst of a disease. Speaking of the diphtheria bacillus he insists that it is not ubiquitous. It is found only in patients and carriers of the two classes. The accidental carrier contracted his germs from an active focus of disease in man or some animal. The more this possibility is studied the greater the likelihood of tracing these bacteria to a focus.

The other objection, that carriers' germs are very largely nonvirulent, also falls to the ground if the inoculation tests are followed up persistently. There is absolutely no difference in this respect between carriers' germs and patients' germs. Another point of interest attaches to the fact that carriers have no real security. They can be and are infected at times from their own germs. The proportion of carriers to patients, as shown by extensive studies in schools and institutions, varies from 1 to 1 to 3 to 1. A genuine campaign against carriers necessarily involve hardships, for the theoretical requirements are very exacting. It remains to be seen whether it is practicable and whether the results bear out the theories; and this will requrie years.

A New Induced Symptom.

An excellent subject for a dissertation is "induced symptoms," the number of which is constantly increasing with the rapid progress of science. Naturally any powerful drug given solely for therapeutic ends may induce certain symptoms which have a diagnostic significance. The first one that occurs to us in this connection is the severe iodism sometimes unexpectedly developed during an iodine cure, which is, or was, believed to indicate impaired renal activity if not actual organic disease. Our lists of contraindications of remedies refers to the same principle. We are warned not to exhibit certain drugs to certain patients lest they develop certain accidents, and naturally the latter, when produced intentionally, must have diagnostic value for the patient's particular type of disease. Some of these induced symptoms have a special forensic bearing and enable us to detect simulation. A point of great significance is the moral right to make use of some of these tests, which produce more or less stormy reactions in a subject already, perhaps, badly off with his disease. At a recent meeting of a Vienna medical society (*Münchener medizinische Wochenschrift*, July 2) Rusu announced that if forty grams of galactose are given to a subject with cholangitis of any causation, a sharp fever promptly sets in and persists for one or two days. In some cases icterus is associated. In recovered individuals double the dose caused no rise of temperature whatever. The explanation is that galactose acts in these cases as a cholagogue, but as the bile cannot escape, it is again absorbed along with toxins of the disease.

Physiological Suicide.

This term has some vogue to designate cases of suicide, however caused, in which the subject is not the victim of a psychosis and is able to give good reasons for his act. Naturally it antagonizes that view which makes every suicide, if not actually insane, at least momentarily unbalanced sufficiently to paralyze the instinct of self-preservation. At a recent session of the physicians of Charité Hospital, Berlin (*Deutche medizinische Wochenschrift*, July 18) Forster, an alienist in charge of an institution, refused to receive as a patient a man who had just attempted suicide on account of disappointment in love because there was no evidence of a psychosis. He would have admitted him at his own request, but as the individual did not choose this course he was allowed to go his way despite the fact that he threatened to make further attempts on his life. Forster defends this course, and compares this case with that of the men or women who love only once in a lifetime, and who, if disappointed in this quest, never marry. Now, while these individuals are often unbalanced, yet this "single-love" obsession, or whatever else it may be, is never evidence *per se* of an unbalanced mind. The suicidal subject showed a heightened excitability which dated from childhood, and perhaps indicated a psychopathic defect, but presented nothing further.

News of the Week.

Infantile Paralysis.—Since July 1 eighty-six cases of infantile paralysis have been reported in Buffalo, N. Y., the disease being widespread throughout the city, not confined to any one district. An odd point brought out is that there has been no occurrence of two cases in any one family. Many of the cases have been of comparatively mild type, and only six deaths had occurred up to August 7. The State Commissioner of Health has requested the assignment of an expert from the Public Health and Marine-Hospital Service to assist in investigating the situation. In Los Angeles, Cal., also the disease is epidemic, 128 cases having occurred there since July 10, with thirty-three deaths. A number of cases have been reported from Baltimore, Md., also.

Typhoid Fever in New York.—The New York Department of Health is puzzled over an outbreak of typhoid fever in a section of Brooklyn. In four days 82 cases were reported from the one neighborhood, and the city milk and water supplies are being investigated. A mild epidemic has also been reported as occurring among clerks and others who pass their business day in the financial district about Wall street in Manhattan.

A Carrier Epidemic of Typhoid Fever.—Between thirty and forty cases of typhoid fever in a New Jersey town have been traced to the milk from one of the best managed dairies in the State. An examination of all the employees of this dairy revealed the fact that the manager was a carrier of the germs of the disease. He had been in his usual health and had presented no typhoid symptoms.

Plague Danger Lessened.—The reports of the plague situation have had a more cheerful tone of late. In Havana the disease, it is said, is practically wiped out, and in Porto Rico it is well under control, no new cases having occurred there since July 30. Following the discovery of one infected rat in New Orleans, some alarm was felt, but the officials in charge report that no other cases of infection have been found in hundreds of rats collected from various parts of the city and carefully examined. One case of the disease has been reported in Liverpool, England, and it is said that the disease is prevalent among the rats there.

Sanitation in Cuba.—Following a recent suggestion that the United States conduct an investigation into the sanitary condition of Cuba, the Cuban Director of Sanitation declares that the island is much more sanitary than is the United States itself, suggests that we do a little cleaning up ourselves, and implies that those who live in glass houses should not throw stones. The constant presence in this country of such diseases as smallpox, infantile paralysis, and spinal meningitis is, he says, a menace to Cuba where such diseases do not exist, and he contends that Porto Rico, an American possession, was the source of the infection of bubonic plague in Havana. In medical legislation it would certainly appear that Cuba is ahead of the United States, since her chief sanitary officer has a seat in the cabinet and all her health officers are Federal appointees.

Cholera in Russia.—The existence of cholera in St. Petersburg was finally admitted officially on August 9. Though no figures were given out, it is said that there are a number of cases and that the disease has been increasing for some weeks. The health authorities have endeavored to suppress the details because, it is reported in the newspapers, of the trouble which publicity would entail in making it necessary to fight the disease.

Medical Aid for Indians.—In a special message to Congress on August 10, President Taft urged the immediate passage of a bill appropriating $255,350 for the establishment of a special medical service for the treatment of Indians. He declared that 296,000 Indians are without medical attention and are being ravaged by disease. The death rate among them is estimated a 35 per 1,000, as compared to 15 per 1,000, which is the average for the country.

The Public Health.—Whatever other matters of contention there may be, all the political parties are agreed on the necessity of caring for the public health. The following is the plank on the subject inserted in the platform of the National Progressive Party: "We favor the union of all the existing agencies for fundamental government dealing with the public health into a single national health service without discrimination against or for any one set of therapeutic methods, school of medicine or school of healing, with such additional powers as may be necessary to enable it to perform efficiently such duties in the protection of the public from preventable diseases as may be properly undertaken by the fundamental authorities, including the execution of existing laws regarding pure food, quarantine, and cognate subjects, the promotion of appropriate action for the improvement of vital statistics, the extension of the registration area of such statistics and cooperation with the health activities of the various States and cities of the nation." The same platform urged the establishment of a Department of Labor whose head should have a seat in the President's cabinet, but the headship of the health bureau is to be a simple salaried position. The doctors have not so many votes as the laboring men.

Dr. Wiley's Successor.—It is reported that Dr. R. E. Doolittle, the present acting chief of the Bureau of Chemistry, will most probably be appointed to that office permanently, succeeding Dr. Wiley. It is known that the President has Dr. Doolittle's name under consideration as one of the few desirable candidates.

Hospital Fires.—The nurses of the Jewish Maternity Hospital, New York, formed a bucket brigade, and before the arrival of the firemen extinguished a blaze which had started in a reading room off the dormitory on the first floor of the hospital on August 5. The damage was only slight.

In the Post-Graduate Hospital, New York, also, on August 9, a fire, the second in three months of uncertain origin, was extinguished by the hospital staff with but little damage to the building and without causing alarm among the patients.

Gifts to Charities.—By the will of the late William Patterson Young of Newark, N. J., $500 each is left to St. Barnabas' Hospital, the Newark Eye and Ear Infirmary, St. Michael's Hospital, and the Home for Crippled Children, all of Newark.

The New York Polyclinic Medical School and Hospital has recently received an additional donation of $50,000 for the New Building and Equipment Fund, and a legacy of $3,000 under the will of the late David J. Garth, Esq., at one time a trustee of this institution.

The New York Eye and Ear Infirmary receives $25,000, and the Presbyterian Hospital, New York, $50,000, by the will of the late John S. Lyle of this city.

Examination for Dental Interne.—The United States Civil Service Commission announces an examination to be held on September 4, 1912, at various places, for the purpose of filling a vacancy in the position of dental interne (male) in the Government Hospital for the Insane at Washington, D. C. The salary is $600 per annum and maintenance. Application for the examination should be made to the United States Civil Service Commission, Washington, D. C.

New Chemical Laboratory.—The Beth Israel Hospital, New York, has just finished the equipping of a new chemical laboratory, where original work will be pursued. The laboratory is furnished with all the most modern chemical apparatus for biological chemical analyses. Dr. Max Kahn has been appointed director of chemical and physiological investigations in the hospital. Visitors to the laboratory will be very welcome.

Clinic in Vienna.—Announcement has been made of the opening in Vienna, Austria, of a clinic for the study of cerebrospinal meningitis, under the direction of Dr. Berthold Beer. The clinic has been founded and endowed as a memorial to the late Mr. E. H. Harriman of New York, and will be open to American physicians studying abroad.

The Health of School Children.—The United States Bureau of Education has recently published the results of an investigation by Dr. Thomas D Wood, professor of physical education at Columbia University, New York, into the health of the school children of this country. Dr. Wood finds that of the twenty million school children in the United

States not less than 75 per cent. need attention for physical defects which are prejudicial to health and which are partially or completely remediable. He draws the following personal conclusions as a result of his investigations: From 1½ to 2 per cent., or 400,000, have organic heart disease. Probably 5 per cent., 1,000,000 at least, have now or have had tuberculosis of the lungs. About 5 per cent., or 1,000,000, have spinal curvature, flat feet or some other moderate deformity, serious enough to interfere to some degree with health. Over 5 per cent., or a million, have defective hearing. About 25 per cent., or 5,000,000, have defective vision. About 25 per cent., or 5,000,000, are suffering from malnutrition, in many cases due in part at least to one or more of the other defects enumerated. Over 30 per cent., or 6,000,000, have enlarged tonsils, adenoids or enlarged cervical glands which need attention. Over 50 per cent., or 10,000,000 (in some schools as high as 98 per cent.), have defective teeth which are interfering with health. Several millions of the chidren possess, each, two or more of the handicapping defects. A similar series of statistics, including only the school children of Boston, which has been compiled by the Boston Department of Health, for exhibition at the Congress of Hygiene next month, shows that of the 118,781 school children of that city over 65 per cent. have physical defects. Of these children 51,340 were found to have defective teeth, and 25,121 suffered from enlarged tonsils. Only 133 were found to be affected with tuberculosis.

No Action Against "Healers."—As a result of the coroner's investigation of the two deaths from scarlet fever occurring in Yonkers, N. Y., recently, the patients being without medical attendance, it has been decided that as the regulations requiring notification of the health authorities had been complied with there is no basis for a prosecution for criminal neglect of the Christian Science healers who were in charge.

New Tuberculosis Hospital.—The King Edward Hospital for the treatment of advanced cases of pulmonary tuberculosis of Winnipeg, Manitoba, was put into active service on July 27, when thirty-five patients were installed. The hospital was formally opened by the Duke of Connaught on his recent visit to the city.

Nurses to Meet in San Francisco.—The International League of Nurses in session at Cologne, Germany, on August 6 elected Miss Goodrich of New York president of the league, and selected San Francisco as the place for the next convention in 1915.

Sioux Falls Medical Association.—At the annual meeting held in Fort Dodge, Iowa, on July 24, the following officers were elected: *President*, Dr. J. N. Warren, Sioux City; *Vice-presidents*, Dr. R. G. Stevens, Sioux Falls, S. D., and Dr. A. E. Spalding, Luverne, Minn.; *Secretary*, Dr. George S. Browning, Sioux City, Iowa; *Treasurer*, Dr. Walter R. Brock, Sheldon, Iowa.

Obituary Notes.—Dr. Frederick Earl Beal of New York, a graduate of the University of Nebraska College of Medicine, Omaha, in 1894, a member of the American Medical Association and of the New York State and County Medical Societies, and of the New York Academy of Medicine, visiting physician to the Northwestern Dispensary, and professor of clinical medicine in the New York Polyclinic Medical School and Hospital, died on August 8 of pneumonia at the Polyclinic Hospital, aged 44 years.

Dr. Joel Smith Thomas, of Pleasant Hill, Illinois, a graduate of the Medical College of Ohio, Cincinnati, in 1872, and a member of the Illinois State and Pike County Medical Societies, died at his home on July 19, after a short illness, aged 67 years.

Dr. David Smith Humphreys, of Greenwood, Mississippi, a graduate of the Medical Department of the Tulane University of Louisiana, in 1885, and a member of the Louisiana State and Leflore County Medical Societies, died at his home on July 20, aged 51 years.

Dr. Otis C. Hollister, of Portland, Oregon, a graduate of the Northwestern University Medical School, Chicago, in 1885, and a member of the American Medical Association and the Oregon State and Multnomah County Medical Societies, died in St. Vincent's Hospital, Portland, on July 17, aged 49 years.

Dr. George M. Anderson, of Tanglewood, Texas, a graduate of the Atlanta Medical College, Georgia, in 1874, a member of the Texas State and Lee County Medical Societies, and a surgeon in the Confederate Army during the Civil War, died at his home after a long illness on July 18, aged 73 years.

Dr. J. Bozeman Letcher, of Shorter, Alabama, a graduate of the Medical Department of the Tulane University of Louisiana, in 1897, and a member of the American Medical Association and of the Alabama State Medical Society, died at his home on July 18, of tuberculosis, aged 38 years.

Dr. Herbert Norris of Philadelphia, Pa., a graduate of the University of Pennsylvania, department of medicine in 1866, and a member of the College of Physicians of Philadelphia, died in Rochester, Minn., following an operation on August 6.

Dr. Christian P. Seip of Pittsburgh, Pa., while attending the sessions of the Pennsylvania Board of Medical Licensure, died at Atlantic City on August 6 at the age of 63 years. He was graduated from the Homeopathic Medical College of Pennsylvania in the class of 1868. He was appointed a member of the Board of Medical Licensure six months ago.

Dr. William H. Palmer of Providence, R. I., died at his home in North Woodstock, Conn., on August 3, aged 83 years.

Dr. William Seymour Johnson of Chicago, Ill., a graduate of the Hahnemann Medical College and Hospital of Chicago in 1868, and a veteran of the Civil War, died at his home from paralysis on July 27, aged 82 years.

Dr. Dwight Edward Burlingame of Elgin, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1869, and a member of the American Medical Association, the Illinois State and Kane County Medical Societies, and the Fox River Valley Medical Association, died at his home after a brief illness on August 4, aged 69 years.

Dr. James L. Lowrie of Lincoln, Ill., a graduate of the Jefferson Medical College, Philadelphia, in 1878, and a member of the American Medical Association, and the Illinois State and Logan County Medical Societies, died at his home suddenly on July 23, aged 60 years.

Dr. Alvin T. Heavenrich of Seattle, Wash., a graduate of the Miami Medical College, Cincinnati, in 1904, a member of the American Medical Association and the Washington State and King County Medical Societies, died in Cincinnati on July 31, aged 30 years.

Correspondence.

THE ICE-BAG IN APPENDICITIS.

To the Editor of the Medical Record:

Sir:—The modest but significant article of Dr. Fauntleroy on the danger of the ice-bag in appendicitis is timely and will doubtless save many lives if its warning note is heeded. I am specially interested in this subject by reason of my connection with the early history of appendicitis surgery and because I have long pointed out the irrationality of the ice-bag in "inflammations." The former was enlarged upon in your issue of March 30, 1912, and does not require restatement here.

The latter is stated as follows in my book on "Hydrotherapy" (published by William Wood & Company), page 149, third edition: "The application of the ice-bag in pneumonia, pericarditis, peritonitis, appendicitis, etc., is so universal that the author opposes this practice with great hesitance and reluctance. The anesthetic effect of a hot poultice or ice-bag cannot be denied, but that such applications can affect the lungs or appendix to any appreciable extent is doubtful. Dr. Henry C. Coe has informed me that he observed while pathologist to the woman's hospital many years ago, no effect upon peritionitis . . . in operations on the living subject he has never seen the slightest effect of the previously applied cold upon the hypervascular condition of the peritoneum. This is the experience of other laparotomists." If a thermometer be introduced into the colon of a dog, its bulb being pressed forward, pushing the abdominal wall into a prominence and ice then be applied over the the latter, there will be no perceptible fall of the mercury so long as the parts are not destroyed. Just as soon as the part is frozen or if the dog is killed, the mercury will drop. The reason is simple enough, but unfortunately is lost sight of as is the physiological basis of other hydrotherapeutic procedures. The author is firmly convinced that the heat regulating machinery of the body is immediately called into action for the purpose of resisting the invasion of cold into the interior and that thus the object of applying the ice-bag is frustrated.

This rationale of the ice-bag does not agree entirely with Dr. Fauntleroy's explanation of the gangrenous condition of the appendix, which he has so often noted in cases that have been subjected to the ice-bag. There is no doubt that the reparative process of "walling off" is interfered with by the ice-bag, but it appears to me that "it deludes Nature" not alone, but also the surgeon, into a false sense of security which by delay favors rapid destruction of the appendix by gangrene in cases pathologically so favored.

I am particularly gratified by the doctor's statement that "it is the invariable rule in the navy to operate in every case in which a diagnosis is made"—a view I have expressed for twenty years. The article referred to concludes: "I would express the result of my observation to be that the number of cases that have been sacrificed by timid procrastination outweigh far the cases in which a fatal issue resulted from premature or unnecessary operation." "When in doubt operate" is a safe decision in acute appendicitis.

Simon Baruch, M.D.

51 West 70th Street.

A SANITARY NOTE FROM THE PAST.

To the Editor of the Medical Record:

Sir: A very prominent writer of sanitary matters has a great deal to say against the congested cities, where crime and ill health seem to revel. Then he turns to the quiet country side, and speaks of the remarkable approach to health and normal living in the low mortality and freedom from disease. Finally he draws a conclusion that no degree of health can be found in the large cities, and that we must go back to the levels of our forefathers of a century ago and live as they did. All this sounds very pleasant and convincing, but unfortunately it is not confirmed by the records of long ago. Away back in the beginning of the century a minister in East Haven, Conn., who may have been a physician and evidently did something along that line, published a little volume in which he put down the history of the town from its settlement in 1664 up to 1800.

This record has the appearance of considerable accuracy and at times it certainly told the exact truth. Thus in 1736 of the 500 people who lived in the town, 26 died of sickness of the throat. In 1742 and '43, with about the same number of people, 60 died from dysentery. From that time up to 1800, a period of sixty years, he estimates the death rate of 30 per thousand for dysentery and 15 for canker rash and so on through various diseases, the names of which are not very clear at present. Evidently the people in that part of the country were not very close to nature in their recognition of the commonest rules of health. In all probability, these and other diseases from which they suffered showed an absence of all common sense rules—bad air, bad diet, neglect of cleanliness, and general dirt and filth.

This little volume is but a hint of what occurred in all other sections, and the most congested cities and defective homes and firesides could not bring worse results. Consumption was very prominent in those days and the methods of treating it simply intensified it and shortened its duration. The resident of the country who recognizes the common sanitary measures necessary for health and applies them in his own home can secure them with greater certainty than the tenant in the crowded cities. There is a great deal to be done in this direction, and boasting of what has been done is not promising for the future.

Hartford, Conn.

A STRANGE FOREIGN BODY IN THE URETHRA.

To the Editor of The Medical Record:

Sir:—In reading Algot Lange's most interesting book "In the Amazon Jungle," I came across the following paragraph regarding an unusual sort of foreign body in the urethra which I have copied from the book as a contribution to that subject.

"Before leaving the subject of fish I will mention another species, smaller than the piranaha, yet although not so ferocious, is the cause of much dread and annoyance to the natives living near the banks of the rivers. In fact, throughout the Amazon this little worm-like creature, called the kandiroo, is so omnipresent that a bath-house of a particular construction is necessary. The kandiroo is usually three or four inches long and one-six-

teenth inch in thickness. It belongs to the lampreys and its particular group is the Myxinos or slime fish. Its body is coated with a peculiar mucus. It is dangerous to human beings because when they are taking a bath in the river it will approach with swift, powerful movement, penetrate one of the natural openings of the body, whence it can be removed only by a difficult and dangerous operation. A small but hard and pointed dorsal fin acts as a barb and prevents the fish from being drawn back. While I was in Remate de Males the local doctor was called upon to remove a kandiroo from the urethra of a man. The man subsequently died from the hemorrhage following the operation."

Most foreign bodies in the urethra are either stones which have become lodged there in passing from the bladder or substances introduced by the individual himself. Occasionally the physician is unfortunate enough to have an instrument break and have part remain lodged in the canal. I do not recall having seen a foreign body similar to the one spoken of in Lange's work recorded and it hardly seems credible that a fish would be able to accomplish so difficult a feat and gain entrance to the male urethra in the way recorded. Its removal would certainly be a difficult procedure armed as it is with the barbed fin.

BRITISH MEDICAL MEETING AT LIVERPOOL—INSURANCE TROUBLES—TUBERCULIN DISPENSARIES—NATIONAL ASSOCIATION AGAINST CONSUMPTION—LISTER—OUT-PATIENT SYSTEM—SIR J. HUTCHINSON—TROPICAL SCHOOL, DR. SEIDELIN.

LONDON, July 26, 1912.

THIS is the British Medical week. The annual meeting this year, as you have been informed, is at Liverpool, a city so well known to traveled Americans (and to others by repute) that it is needless to tell you that it furnishes everything necessary to secure the success of any public proceedings. It should, however, be said at once that the most hearty welcome awaited us on the part of the local profession and also of every class of citizens. So, what between work, recreations, amusements, and social amenities, Liverpool equaled, if it did not excel itself. This is, I believe, the fourth time that the annual meeting has been held here during the eighty years of the Association's existence. This year the work was divided into twenty sections, a fact which indicates to some extent the great progress made in medical and scientific knowledge, and their applications in our art. Your special reporters will give you an outline of some of the proceedings, but cannot possibly deal with the mass, which would fill more than one number of the RECORD; but of course the most important points will come up from time to time in your columns. As to the Association's medico-political and its official work, only a portion may interest your readers. I will mention some.

The Representative Meeting controls the policy of the Association, and its proceedings are kept entirely separate from those of the sections. This body is elective and met on Friday Saturday, and Monday to consider among other things reports of the Council on the Insurance Act, State sickness and the other leading questions at present agitating the whole profession. These meetings are not public and reporters are excluded, but there is practically full publicity and even decisions will have been discussed in all directions before you hear of them. In fact the ubiquitous press, determined not to be outdone, has contrived to get some statements that bear on the public interests, but unfortunately these are not all quite correct. There was no little hot discussion both on Friday and Saturday as to the effects on the profession of the Insurance Act and how the Chancellor of the Exchequer ought to be met. It was held by many that the government had heaped insult upon insult on the profession, and that there was good reason for all to unite to render the act inoperative. Some, on the other hand, were disposed to keep the door for negotiations open in the hope of compelling the Chancellor to give way. The proceedings on these days may be looked upon as in committee. On Monday they were still further discussed and to a great degree confirmed, or so far as was necessary with some deviations to place them before the Council and general meeting. Besides the reports of committees the meeting had before it the reply of the Insurance Commissioners to letters addressed to them and the observations of the State Sickness Committee thereon. The chairman of this, Mr. T. J. Verrall, said their position was all along unsatisfactory because the profession had not been consulted at an early stage, and he had reluctantly to admit that no material concession had been made by Mr. Lloyd George. The committee continued in session the whole day, the one subject being whether to break off negotiations altogether or appoint a committee to negotiate further with the Government. To break off was voted by 185 to 21, but a further ballot had to be taken to confirm it.

A "Tuberculin Dispensary League" has been at work here for a couple of years and the Countess of Mayo, president, held the annual meeting in her house. The object is, of course, to promote serum treatment by establishing dispensaries. The first was placed under the care of Dr. Camac Wilkinson, who attended and reported that 245 new cases were taken in the year and another dispensary was being organized. But for the help of other doctors who attended the dispensary to study the subject, he could not have dealt with all. They relieved 14 out of 31 cases in the advanced stage, with pulses hanging from 120 to 140. In no instance had large doses had ill effects, showing tuberculin could be used in all stages. In four fatal cases in the two years there had been mixed infection. He contrasted the slight cost of this method with that of one of the consumption hospitals, but the cases are not parallel, and his remarks thereupon have given rise to just criticism. He is an enthusiast, but even so there is no need for any assumption when "urging in all modesty that their system should be studied" before locking up money in hospitals.

A kindred organization, the National Association for Prevention of Consumption, held its meeting on Tuesday, Lord Balfour of Burleigh presiding. He said they were getting people educated to the value of cleanliness and sunshine and that infection was a reality in consumption, which was not hereditary in the general sense, but perhaps as a predisposition. Some people objected to much of the Insurance Act, but this Society would help it heart and soul. He deeply regretted recent resignations and hoped the incident would not harm the cause. Some had said they were not active enough. He

pleaded not guilty and thought the annual report an admirable answer to such a charge. None of the dissatisfied had offered a practical suggestion that they had rejected. If he were disposed to carry the war into the other camp he might say there were at least two of those gentlemen who had never attended a meeting of the Council since they were appointed.

The committee for establishing a memorial to Lord Lister met at the Royal Society on Monday. Sir Archibald Geikie, president of the Society, was appointed chairman and the Hon. W. F. D. Smith deputy chairman of the committee. An executive committee was appointed and discussed proposals. Arrangements have been made for a public meeting in October at the Mansion House, when probably a scheme will be announced; perhaps it may include the erection of a monument in Westminster Abbey.

The committee for inquiring into the out-patient system issued a report yesterday. They find the number might advantageously be diminished, and some arrangement might be made for treatment elsewhere.

Sir Jonathan Hutchinson on Tuesday celebrated his eighty-fourth birthday. His colleagues of the Council of the Royal College of Surgeons sent a letter to their ex-president and emeritus professor expressing their appreciation of his devotion to science and surgery and referring to the numerous academical honors conferred upon him. Sir Jonathan sent on the occasion a cheque for 50 guineas to the British Medical Association toward the cost of the fight against the Insurance Act, together with a letter stating his firm belief that an ill-paid profession would be a calamity to the community, and the niggardly proposals of the government a gross injury to medical education and training.

Sir William H. Lever, chairman of the Liverpool School of Tropical Medicine, gave a banquet on Monday in honor of Dr. Harald Seidelin on his return from the Liverpool yellow fever expedition to Yucatan. Sir William declared that Dr. Seidelin had made discoveries which would greatly promote the study of tropical diseases and therefore benefit all who lived there or had to go there for a time. Prof. J. L. Todd believed the day would come when Europeans could live as safely in tropical as in temperate climates.

OUR LETTER FROM THE PHILIPPINES.

(From our Regular Correspondent.)

THE MOSQUITO PROBLEM—MEETING OF THE MANILA MEDICAL SOCIETY—A CASE SIMULATING LEPROSY—DIARRHEA IN CAMP—DISEASES PRESENT IN THE BATANES ISLANDS.

MANILA, June 14, 1912.

THE mosquito campaign which has been conducted in Manila during the past year and a half, and which met with considerable success, has had a sharp set-back during the past few weeks. Heretofore, the mosquitos that have been annoying to man in Manila have been the *Stegomyia perstans*, which flies during the day, and the *Culex fatigans*, which is a night flier and is supposed to be responsible for the transmission of dengue and filariasis. Accordingly, the campaign has been directed entirely against them, with the result that it is possible to sit on verandas and other open places in the evening, in comparative comfort, which was impossible prior to the beginning of the campaign.

During May and June of each year Manila has its extreme high tides. The highest of these sometimes reaches several feet above the ordinary tides, and this results in much additional lowland being overflowed and water being backed into some of the higher pockets which do not drain. In these, a small black mosquito (*Culex ludlowii*) breeds very profusely, and as oil flows off at each high tide, the only hope for permanent relief would be along engineering lines, and this would require an amount of draining and filling which is beyond the resources of the city to supply, so that, for some weeks it is to be expected that Manila must be again inconvenienced by mosquitos.

The mosquito problem has been further complicated by the fact that it has been again asserted that the *Myzomyia rossii* is responsible for the transmission of malaria. In view of the fact that no anophelina, even after most diligent search, have been found anywhere in the Philippine Islands (with the possible exception of one single specimen which is alleged to have come from the Philippines, and which is now in Washington), and on account of the very general prevalence of malaria throughout the Philippine Islands, and that *Myzomyia rossii* is always found in sections in which the disease is present, and that the anopheles in these sections are conspicuous by their absence, lends considerable confirmation to the belief that this mosquito may be concerned in the transmission of malaria. *Myzomyia rossii* has recently been found in fish ponds in Manila, and difficulty is now being encountered with the owners of these ponds because they object to the destruction of the algæ upon which the larvæ feed and which, in turn, serve as food for the fish.

The regular monthly meeting of the Manila Medical Society was held on the roof of the building of the College of Medicine and Surgery, at 8:30 P.M., June 3. Two clinical cases were shown by Dr. Sison, of the Philippine General Hospital; one, a case of pseudomuscular hypertrophy, and the other, a case resembling a mild tetanus, but in which no diagnosis had been made. A third case was shown by Major Ashburn, that of a child, 5 years of age, who had been reported to the Bureau of Health as a suspect leper. Upon examination, the diagnosis could not be confirmed. The child had a solid, roseolar eruption, with marked induration, on the forearms, hands, legs, and feet. The palms of the hands and the soles of the feet showed marked callus. There was, evidently, considerable disturbance with the blood supply. The little finger of the left hand had, near its base, a marked constriction resembling ainhum. The little toe of the right foot had apparently been partially absorbed or worn away. The hands were stiff, and with the exception of slight motion of the fingers they were almost useless. On this account, it was evident that the callus was not due to use of the hand. Previous examinations had been made for leprosy bacilli, but with negative results. The condition was evidently an endarteritis. The Wassermann test was markedly positive, and it is now proposed to treat the child with salvarsan and note the result.

The first paper entitled "Dysentery at Baguio," by Doctors Barber and Gomez, was read by the former. A brief account was given of the acute outbreak of diarrhea which occurred at Baguio, the mountain capital of the Philippines. In all, 23 hospital cases came under observation, and of these, 10 died. The laboratory investigation

showed the presence of either the Flexner or the Shiga type of organism in every case. Dr. Barber stated that the routine technique had been used in isolating the bacilli. Smear preparations made by applying a slide directly to the rectal mucosa showed large numbers of bacillary organisms and very few colon organisms. A series of water examinations made by the authors lead them to conclude that water transmission was not a factor in this outbreak.

The next paper, entitled "Diarrhea at Camp John Hay," by Drs. Ashburn and Vedder, was read by Dr. Ashburn. Camp John Hay is the army post located at Baguio, and the object of Dr. Ashburn's paper was to report upon the diarrhea which had taken place among the troops at the time the civil population was affected. During February, an acute, explosive outbreak of diarrhea occurred among the members of one company. Investigation showed that prior to the outbreak the cook of the company had been suffering from diarrhea. Agglutination tests made of his blood two months later showed the same to agglutinate in dilutions of 1 to 20 with the Shiga bacillus. The blood of all members of the company who had been afflicted with the disease agglutinated in dilutions ranging from 1 to 50. The agglutinations among the controls were negative except in the cases of two Igorrote kitchen boys in whom agglutination tests of 1 to 20 were encountered. The investigation made by the authors did not take place until April and in May, which was two months after the acute outbreak, but they did, however, encounter two cases in which the Flexner type of organism was found. The writers concluded that the outbreak was directly due to contamination of the food supplies by the cook, who probably became infected from the two Igorrote kitchen boys who showed positive agglutination tests, and that the water and fly transmission might be safely excluded, and that the diarrhea which had occurred in the last few years in Baguio had, presumably, been bacillary in its nature.

In the discussion which followed, Dr. Heiser stated that the profession owed a large debt of gratitude to the authors of the two papers which had just been read, because the etiology of the Baguio diarrhea which had been so obscure heretofore had been placed upon a scientific basis. In the past, many practitioners had been inclined to place the diarrheas of Baguio in the category of the so-called "hill" diarrhea or mountain diarrhea, or to acute intestinal disturbances due to sudden changes in climate. Other practitioners were of the opinion that the diarrhea was due to the sudden chilling owing to the low temperature, and the disturbance of blood pressure by the altitude of Baguio, which is 5000 feet, and by the failure to provide proper protection to the abdomen with flannel bands at night. All these reasons were very unsatisfactory, and from an epidemiological standpoint were not susceptible to reason. For instance, he stated that, upon the transfer of some 600 Government employees to Baguio during the latter part of February, ten per cent. of the employees were afflicted with diarrhea soon after arrival, but investigation showed that the disease prevailed among persons who were permanent residents to an even greater extent, so that the sudden change to the lower temperature and higher altitude could scarcely be held to account for the diarrhea among the new arrivals. He also pointed out that, this year, on account of the very general use of distilled water, the water transmission of the disease could be excluded with reasonable certainty. He stated, however, that investigation had shown that a new railroad was being constructed with laborers imported from districts in which bacillary dysentery undoubtedly prevailed, and that the sanitation of the camps in which these laborers lived was defective. The excreta was not protected from flies —of which a veritable pest was present in Baguio at the outbreak of the dysentery. It seemed not improbable that flies may have been concerned in the transmission of the disease. He also stated that subsequent investigation had shown that many of the dishes used by Filipino employees had been washed in the overflow from the septic tanks, and that the discharges from these tanks had been shown not to have undergone proper bacteriolytic action. He stated that the insanitary conditions at Baguio were due largely to the fact that the town had been developed at the expense of sanitation; the advice of the medical man had gone unheeded, and no funds were provided to carry out such necessary sanitary measures as proper disposal of garbage and sewage, and that it was only when the community became alarmed at the large number of deaths from dysentery that funds became available for installing a few temporary or emergency disposal systems. The campaign which had been waged against flies had been reasonably successful, and, at all events, the reduction in the number of flies corresponded with the great reduction in the number of cases of diarrhea.

The next paper was entitled "Diseases Prevalent in the Batanes Islands," and was read by Dr. D. G. Willets. The Batanes Islands are a group north of the Philippine archipelago, and south of Formosa, and, on account of the very infrequent communication with the civilized world, they have not suffered so much, especially from the dangerous communicable diseases, as have other sections of the Philippines. The population of the islands is, roughly, 12,000 persons. There is not a medical man among them. Dr. Willets found the usual diseases. He examined, for instance, the stools of 400 persons, in which he found two cases of amebæ, one balantidia. Sixty-six per cent. had ascaris lumbricoides; 26 per cent. had hookworms, and the entire 400 were afflicted with at least one parasite. A fever, on the island of Isbayat, which is greatly feared by the natives, was investigated by Dr. Willets. The symptoms led him to believe that it was malaria, but the spleen examinations which were made of the several hundred persons in the affected area only showed marked enlargement in one case. Numerous blood examinations failed to reveal any parasites. Later, Dr. Willets contracted a fever himself, and demonstrated the estivoautumnal parasites in his own blood. Since the symptoms corresponded so closely with those which had been described to him, he concluded that the fever was due to malaria. He found a number of cases of hemoptysis, but repeated examinations for tubercle bacilli and *Paragonimus westermanii* were negative, and he concluded that the disease must be chronic bronchitis, because this disease is very prevalent. Dr. Heiser suggested that possibly the hemoptysis might be due to oidium, but as no examination had been made for them it was impossible to state.

The next paper was a preliminary report on some nutritional experiments by Dr. Shacklee.

Progress of Medical Science.

Boston Medical and Surgical Journal.

August 1, 1912.

1. Institutions for the Prevention and Cure of Tuberculosis as Elements in the Social Defense Against the Disease. E. O. Otis.
2. Specific Treatment Against Pulmonary Tuberculosis and Its Complications. One Hundred Tuberculous Patients Treated with Bacterins and Tuberculin. J. A. Lyon.
3. On Some Recurrent Febrile Attacks in Chronic Pulmonary Tuberculosis. C. E. Edson.
4. A Laboratory Course in Physiology Based on Daphnia and Other Animalcules. G. V. N. Dearborn.
5. The Argument for the Large State Insane Hospital. W. Channing.
6. The Prognosis in Dementia Precox. A. W. Stearns.
7. The Gastrointestinal Disturbances Observed in Pernicious Anemia. J. Friedenwald.

1. Elements in the Social Defense Against Tuberculosis.—E. O. Otis states that the institutions or organizations which are more directly and intimately concerned in the prevention and cure of tuberculosis, and which exercise a definite stimulating and educative influence upon society in its defense against the disease, are comprised in the following enumeration: (1) The sanatorium; (2) the tuberculosis dispensary; (3) the "tuberculosis class," first instituted by Pratt of Boston; (4) the open-air school; (5) the day and night camp; (6) the "preventorium," so-called; (7) anti-tuberculosis associations or leagues, national or local, some of which are purely sources of education by means of the tuberculosis exhibition, lectures, literature, the public press, etc., while others undertake creative work, such as the inauguration and maintenance of sanatoria, dispensaries, hospitals for advanced cases, visiting nurses, etc.; (8) compulsory instruction upon tuberculosis in the public school, such as is now required in the public schools of Massachusetts, and doubtless in other progressive communities.

2. Vaccine and Tuberculin Treatment of Tuberculosis.—J. A. Lyon notes that mixed infection is usually present in progressive pulmonary tuberculosis and its complications. Therefore the use of appropriate vaccines is essential, either before the administration of tuberculin or conjointly with the latter. In many catarrhal cases great benefit is derived from polyvalent colon vaccine or, where this fails, an autogenous one made from the colon bacillus found in the feces. In the later stages of tuberculosis or in toxemic cases, the purified tuberculin, if given in appropriate dosage and under due precautions, is a useful adjunct to sanatorium treatment. The improvement in the general condition, due to the checking of the intercurrent infection, enables the tuberculin to act favorably upon processes which, had the concomitant bacteria been disregarded, would certainly be more refractory, if amenable at all.

3. Recurrent Febrile Attacks in Tuberculosis.—C. E. Edson notes that certain individuals with chronic pulmonary tuberculosis give a history of repeated attacks of fever, lasting a week to ten days or more and gradually subsiding. The recognition of these cases rests chiefly upon two factors: First, the repetition of attacks without adequate cause in cases otherwise under conditions favoring improvement, and without any evidence of tissue change corresponding to the constitutional signs; and second, a certain regularity of the periods of recurrence. In seeking an explanation of the attacks, it appeared that they occurred usually in patients with rather extensive involvement of the pulmonary tissue, such as would lead to generally lessened power of oxygenation; in patients who were especially careful in maintaining their nutrition at a maximum, and in avoiding over-exercise; and who were especially conscientious in their obedience to régime The attacks were apparently of pulmonic origin. That they were due to accumulated unoxidized pyrogenous material, however, seems probable, if not proven by the prompt and often complete relief obtained when such an origin was made the point of therapeutic attack. The chief reliance and the best results have come from recognizing the nature and cause of the attacks, and following the indication for a greater amount of exercise in the intervals; and, when necessary in addition, anticipating each recurrence by a course of salicylates for a few days every four, six or eight weeks, as the case might be. Under such régime it has been possible to abolish some attacks entirely; and so to lessen the severity of others as greatly to improve the physical condition and progress of the patient, and relieve him from the gloom of a supposed intractable tuberculous fever.

6. The Prognosis in Dementia Precox.—A. W. Stearns calls attention to the following facts: (1) The apparent hopelessness of dementia precox so far as mental health is concerned. (2) The high mortality, especially from pulmonary tuberculosis and other pulmonary affections. (3) The probability of subsequent relapse, even though the patient apparently recovers from the first acute attack. (4) The large number of cases requiring permanent hospital care. (5) The danger of mistaking atypical depressions for catatonic dementia precox.

7. Gastrointestinal Disturbances in Pernicious Anemia.—J. Friedenwald has studied a series of fifty-eight cases of pernicious anemia, in all of which gastrointestinal symptoms were noted. Of these cases there were forty-nine males and nine females, the ages ranging between thirty and sixty-two years. In all of these cases complete blood examinations had been made, and only those have been included in the report in which the physical characteristics as well as the examination of the blood left no doubt as to diagnosis. The symptoms manifested were loss of appetite, nausea, vomiting, indigestion (fullness, pressure, distention), diarrhea and constipation. A large proportion of these cases were attended with gastrointestinal disturbances as well as with an absence of gastric secretion; there was present an achylia gastrica in about 70 per cent. of the cases and even in the stage of apparent recovery the gastric secretion did not return. In a smaller proportion of cases, 20 per cent., there was a marked diminution of the secretion, and in a few instances, about 10 per cent., it remained normal. The author concludes that it is quite probable that the poison which produces the hemolysis is also responsible for the alteration in the gastric secretion.

1. Advantages of a Cold Dry Climate.—A. D. Blackader extols the stimulating and health giving properties of the steadily severe but dry cold of northern Canada, and especially of the Laurentian plateau. The effect of cold air on the body is twofold. First, there is an actual abstraction of heat, which is rarely desirable, and which, so far as possible, should be prevented. Second, cold has a stimulating action on the peripheral nerve endings, strengthening respiration and circulation, and improving oxidation and nutrition. Cold fresh air favors natural sleep, and stimulates the appetite and digestion. In inflammatory conditions of the larynx and trachea cold air may act as an irritant and do definite harm. Individuals suffering from organic diseases of the circulation as a rule stand cold poorly. In a few instances the cold may rouse to in-

creased activity the defective powers of compensation and distinct improvement may set in, but too often an efficient reaction fails to be elicited and the severe cold leads to disastrous results. Anemic patients, as a rule, do well, but require caution in maintaining body heat. In cold weather the eliminating functions of the skin are very slight and toxic materials in the system are thrown off almost entirely by the kidneys and intestinal tract. To benefit from a winter in the north both sets of organs should be in healthy working order. Extreme cold is not desirable for cases of gout, arthritis, or neuritis. For those suffering from advanced degeneration in any organ, for those advanced in years, and for the very young, extreme cold may be distinctly harmful.

7. **Tumor Genesis.**—G. L. Rohdenburg and F. D. Bullock conclude that tumor formation, whether benign or malignant, starts as a localized process at some focus of healing which is usually microscopic, and may either follow a physiological process or be due to extrinsic causes. Either because of the mode of cell death, or for reasons at present not clear, the products of nucleoprotein hydrolysis are not removed by the phagocytic action of the leucocytes. The continued application of certain stimuli causes either benign or malignant new growths, depending probably on the amount and continuation of the stimulus, while the type of tumor depends upon the type of cell involved. Such an hypothesis would explain the many puzzling features of tumor formation, for example, autonomous growth, changes from benign to malignant tumors, changes in tumor types, age, sex, and tissue incidence, and at the same time correlate the at present widely divergent findings in tumor biology.

10. **Female Pelvic Disease and Mental Disturbances.**—E. A. Schumann states that operations of necessity should be performed wherever indicated, whatever the mental state of the patient. Purely elective operations should not be performed upon the insane unless, after careful consideration and study of the indications with the alienist, it is determined that the benefits accruing from the operative procedure will more than counterbalance the shock and strain incident to the anesthesia and the pain involved. Operative procedures designed merely to produce some reflex or other not understood effect upon mental disorders, and practised without definite pathological basis, are absolutely unjustifiable and are to be condemned. To this class belong the extirpation of healthy ovaries, indiscriminate dilatation, curettage, etc. The keynote of gynecological treatment among the insane is conservatism. The insanity already present must be considered as a serious contraindication to any surgical interference, and only when the apparent benefits of an operation of any character whatever are considerably in excess of the risks of an exacerbation of the mental disease, should such interference be suggested.

4. **Diagnosis of Pathological Conditions of the Liver.**—I. C. Chase concludes that the urobilinogen test is a very delicate test for impaired liver function. Any localized diseased cells will let pathological amounts of urobilinogen pass to the urine. The galactose test, on the contrary, is a general functional test. Galactose is not passed in localized hepatic diseases when the remaining part of the liver has good compensatory function. In the various forms of cirrhosis the galactose test is uniformly positive, being strongest in alcoholic cirrhosis. In septic conditions or advanced stages of infectious diseases a positive galactose test results from liver degeneration. In cases of phosphorus, chloroform, and mineral poisoning, liver degeneration is not shown by the galactose test until some days after the administration of the poison; in phosphorus poisoning, sometimes not until the second or third week. The great value of these tests for differential diagnosis lies in the conclusions which can be drawn from their combined use.

5. **Tuberculin Treatment of Pulmonary Tuberculosis.**—H. L. Barnes reports the results in 150 cases of pulmonary tuberculosis treated with tuberculin at the Rhode Island State Sanatorium during the five years from 1907 to 1912. The tuberculin was administered according to the method of Trudeau, an effort being made to develop tuberculin tolerance by gradually increasing doses. Slight general reaction occurred in 20 per cent. of the cases. Fifty-six of the patients were given watery extract, forty were given old tuberculin, thirty-seven were given bacillus emulsion and the remainder the bouillon filtrate. A portion of the patients did not take the treatment as long as advised, because they could not see any effect from it. In a few cases striking improvement occurred; equally striking results occurred under ordinary treatment, and on the whole the patients did neither better nor worse than patients not so treated. The average duration of sanatorium residence for the tuberculin-treated patients was 11.1 months, against 5.1 months for those not thus treated. The analysis furnished no evidence that these 150 patients taken as a whole were influenced by the tuberculin treatment.

8. **Parakeratosis Ostracea (Scutularis).**—L. Weiss describes a case of this condition of which little has been reported in the literature up to the present time. He agrees with Unna that it is an anomaly of cornification attacking the body in groups and combined with inflammatory phenomena which penetrate deeply and produce peculiarly formed cones. He differs from Unna, however, in not considering the infection microbic. He suggests the specific name "ostracea" as more descriptive of the appearance than "scutularis."

10. **Operative Treatment of Fractures and Disloca-**

tions.—By W. Darrach. (See Medical Record, June 29, 1912, page 1249.)

11. **Constipation and Headache in Women.**—C. A. L. Reed discredits the common view that the constipation and headaches frequently complained of by women with gynecological derangements are due to the latter, and holds that the chief cause is to be sought in displacement or ptoses of the abdominal and pelvic organs. He has observed so many cases in which these symptoms persisted after all gynecological indications had been met that he feels that the work of Glenard fairly supplies the missing link in the etiologic evidence. The usual displacement is a general descent of the bowels by which the cecum finds its way low into the pelvis, lowering the transverse colon and hepatic flexure with obstructive angulation at the latter and at the splenic flexure. These displacements are not always accompanied by the uncomfortable symptoms; in some cases they may exist with a fair degree of health, but the frequency with which their diagnostic importance has been confirmed by surgical explorations by himself and others, and the uniformity with which they have been relieved by correction of the displacements, have convinced him that such ptoses are frequent causes of pelvic mischief and general disturbance of health in women.

12. **Iodoglycerole in the Treatment of Mouth Infections.**—E. S. Talbot applies this name to a preparation consisting of water, 2 parts; zinc oxide, 3 parts; iodine crystals, 5 parts; and glycerine, 10 parts. He notes that as compared with the ordinary tincture of iodine, its astringent properties are greatly increased; glycerine causes rapid absorption and the irritating effects are reduced to a minimum. The penetrating effect is remarkable. The glycerine thickens the preparation and prevents it from mixing with the saliva and running over the mouth, as the ordinary tincture will do. This preparation may be used on the gums every day, if necessary, without injuring the parts. The teeth as well as the soft parts of the mouth should be treated in like manner. The author has been able to reduce decay of the teeth in his patients by the use of this preparation from 30 to 40 per cent. All patients receive this treatment before or after each sitting. He finds it especially useful in cases with bone disease, such as caries, necrosis, osteomyelitis, and on all pus surfaces.

15. **The High-Calory Diet in Typhoid Fever.**—By W. Coleman. (See Medical Record, June 8, 1912, page 1119.)

16. **Subdural Injections of Epinephrin in Experimental Poliomyelitis.**—B. F. Clark has found that a subdural injection of epinephrin was capable of producing a marked change in the character of the paralytic phenomena in experimental poliomyelitis, although the effects were not equally striking in all cases. The general result was an improvement in the tone of the paralyzed muscles and in the respiratory movements. In some animals the effects were striking, and a state of extreme flaccidity and unconsciousness with almost complete disappearance of reflexes was succeeded by one of tonus, of strengthened reflexes and of return of consciousness. Life was apparently prolonged in these cases. In another case there was no definite proof that life was prolonged, and the symptoms were only moderately ameliorated. An examination of the two classes of cases would seem to show that the employment of the epinephrin relatively early in the course of paralysis does not in the monkey inoculated intracerebrally with a highly active virus bring about an arrest of the progress of the disease. The life-saving action of the epinephrin is shown in the case of the moribund animals, in which life was prolonged either for several hours or for several days by the restoration of the failing respiratory function. Finally, the effects of epinephrin in experimental poliomyelitis support the view that a state of hyperemia of the blood vessels attended by an exudation of plasma and probably of cells also precedes the severer state of destruction of nerve-cells and interstitial tissue of the spinal cord. They indicate further that subdural injections of epinephrin in proper doses may be found capable of averting in human beings, the subjects of ascending forms of poliomyelitis, a fatal issue through the involvement, in the extending hyperemia and inflammatory edema, of the nerve-cells from which the phrenic nerves take their origin. Should this temporary interruption of the active pathological process coincide with the natural limitation of the disease, even life may be spared. The experiments do not indicate that epinephrin itself contributes in any way to the promotion of the limitation of the lesions. Epinephrin is not a curative drug in the sense that it acts on and neutralizes the poliomyelitic virus. Any favorable effect that it may produce results from its action on the blood vessels and the consequent control of exudations.

3. **Syphilitic Lung Affections.**—H. C. French states that in early secondary syphilis bronchitis is not infrequent, but is usually attributable to the use of mercury or potassium iodide, or supervenes as an accidental factor. Syphilis may be responsible for pneumonia in the early secondary stage. The pneumonia may be of septic origin, possibly due to ulcerative conditions in the mouth, or to carious teeth giving rise to septic intoxication.

5. **Distribution of Chloroform in the Blood.**—G. H. Clark and D. Lindsay present evidence that in rabbits the blood contains a larger proportion of chloroform in the plasma when the anesthetic is given subcutaneously than when it is given by inhalation. This is considered to be the reason for the delay in elimination and the consequent greater injury to the tissues which is associated with the former mode of administration.

6. **Unusual Forms of Meningitis in Infancy.**—E. B. Smith and A. W. G. Woodforce report the histories of two rare cases of meningitis. The interesting features of the first of these were as follows: (1) The long duration of the case—fourteen weeks; (2) the appearance in the first instance of a suppurative meningitis due apparently to a leptothrix alone; (3) the slight initial symptoms associated with this form of suppurative meningitis; and (4) the apparent tendency to recovery from this infection which was prevented by the very unusual sequence of a secondary infection of the meninges by the tubercle bacillus. It may be said that this was really all the time a double synchronous infection and not a successive condition; in opposition to this view the authors state that the sudden onset, the preliminary stages, the appearance and contents of the cerebrospinal fluid, and especially the long duration of the illness, were all against an original tuberculous infection. The second case reported was one of colon bacillus meningitis. From a review of the re-

corded cases it would appear that primary *B. coli* meningitis is a disease of infancy and manifests itself in two forms—as a serous meningitis and as a suppurative meningitis. Further consideration shows that as regards symptoms the disease is indeterminable from other types of acute meningitis, while as regards prognosis it is by no means invariably fatal. Only 50 per cent. proved immediately fatal. Recovery may be presumably complete or be attended by sequelæ such as may follow any acute meningitis—namely, mental deficiency, hydrocephalus, loss of special senses, etc. A differential diagnosis from other types of meningitis can only be made by a careful examination of the cerebrospinal fluid.

7. **Pulsating Exophthalmos.**—R. R. James and W. F. Fedden note that cases of pulsating exophthalmos are not very common, only about twenty having been published in England. Ligature of the carotid appears to have been practised in about half of these cases. Two cases of this condition are reported by the authors. Both cases are regarded as examples of arteriovenous communication, presumably in the cavernous sinus, secondary to a fracture of the base of the skull.

Münchener medizinische Wochenschrift.

July 23, 1912.

Palliative Treatment of Prostatic Hypertrophy.—Joseph refers to cases ineligible to operation and self-catheterization—old, decrepit, poor subjects with defective mental powers. Something must be done to remedy these cases, and one of the more recent customs is the establishment of a suprapubic fistula, into which a urinal may be fitted. While the idea is sound, the technique thus far evidently leaves much to be desired. The author, who is assistant to Professor Tietze of the Mikulicz clinic, Breslau, has devised a procedure which has given good results in urinary retention of all kinds. With bladder filled to the limit patient is placed in the Trendelenburg position and an incision 1 cm. long is made in the median line a finger's breadth above the symphysis. Through this opening a trocar is passed into the bladder, and the cannula left in situ, and through the latter a catheter is introduced until the bladder contents begin to escape. The catheter may be worn in the fistula without any retention apparatus. It is provided with a stopcock and whenever the patient feels the desire to urinate he turns it. There is no escape of urine around the catheter. If leakage develops later the catheter may be removed for twenty-four hours, whereupon retraction occurs of itself. Every four or five weeks catheters should be changed.

Pituitrin as a General Postoperative Tonic.—Jaschke refers especially to the good effects of pituitrin on the bladder. It was discovered by accident that a favorable action occurred in this respect after confinement, and it was then ascertained that after operations in which pituitrin was used there was less demand for the catheter. At the same time a favorable action has been noted on the intestinal peristalsis. When we bear in mind the known effect of the drug on the vascular tonus the conclusion lies near that pituitrin may be regarded as a general tonic to all smooth muscle. The author has used the remedy in a series of 44 operations in the field of abdominal surgery. In nearly half of this number the patients did not require a catheter at any time. The others were not blameless in this respect, but in the majority of these the return of spontaneous micturition was not delayed beyond the second or third day. In delayed cases it was customary to repeat the doses. The author seems inclined to use pituitrin after any operation in which the cardiovascular apparatus may benefit by artificial support, while its additional power over the bladder is also welcome.

Acetonemia in Children from Fat Ingestion.—Silberstein states that acetonemia in childhood is associated with markedly coated tongue, vomiting, pallor, and fever. This syndrome sometimes follows the ingestion of cod liver oil. Repeated attacks in the same child have been traced to the ingestion of whipped cream, milk, cheese, etc. A fruity odor of the breath and acetone in the urine usually accompany these attacks. Naturally a marked individual disposition in this affection must be present, as a result of which acetone bodies are split off from the diet fat. In other words, an intolerance is present, and doubtless the kind of fat cuts no figure, while direct ingestion of fatty acids might of itself cause the picture. The treatment consists of alkalies (soda) at the outset, followed by pepsin—HCl.

Deutsche medizinische Wochenschrift.

July 18, 1912.

Is Sympathetic Ophthalmia Due to Anaphylaxis?—Peters emphasizes the shortcoming of all of the old theories respecting the nature of this affection. Hence it is inevitable that a theory of anaphylaxis must be tested and this has been done of late by Elschnig. The latter has shown that eye pigment has a pronounced antigen action of an organ-specific character. The arguments in favor of an anaphylactic causation are at present inferior in force to any of the older views, and the only reason to advance the theory is simply because no further ones are available. From the anaphylactic viewpoint it would have to be assumed that pigment absorbed from the disintegrating eye is able to sensitize the other eye. This of course could cooperate with some other causal element.

Treatment of Scars.—Kirchberg, an authority on massage, contributes a study of scar treatment on a basis of manipulation, the latter being peculiarly adapted to meet the different indications. The intense itching, the pressure pains due to retraction, the disfigurement, disability, the likelihood of scar keloid and scar cancer developing, the susceptibility to injury, all furnish indications for treatment. The author divides scars into (1) flat, level with skin, mostly white; (2) deep, atrophic and (3) hypertrophic. The first variety is chiefly a blemish of cosmetic significance only, and may be tattooed in such way as to conceal them. In the deep, atrophic form, the subjacent adhesions must be detached. While treatment of pittings from small-pox and acne is on the whole unsatisfactory, some excellent results have been secured by massage, but this must often be kept up month in and out. The movements consist of surface frictions with finger tips, the skin also being pushed or pulled back and forth over the subjacent bones. The manual massage must be supplemented by vibrations. Even after many years this treatment may be begun with good prospects for success. Hypertrophic scars require special measures—compression with plaster, fibrolysin, etc.

Utility of Oppenheim's Nutrition Quotients.—Von Sohlern refers to Oppenheim's attempts to secure certain coefficients for expressing the state of nutrition of an individual—such for example as the chest girth divided by the measurement of the biceps. He finds this idea of small merit for adults. The two quotients by themselves give but little idea of the nutrition. Oppenheim had advanced the idea that the quotient given above plus another in which the dividend was the chest girth multiplied by the arm girth and the divisor the height of the subject would be fairly indicative. It is possible that a trustworthy method might be developed along these lines but it would be too cumbersome for practice.

Insurance Medicine.

The Treatment of Substandard Risks.—John C. Cameron says that there are four recognized methods of treating substandard lives, taking the term for the present to embrace borderline cases: (1) To limit the plan of policy. (2) To grant the policy applied for at the ordinary rates but subject to a fixed or decreasing reduction during a given period—this being known as the lien plan. (3) To rate up the life by a certain number of years. (4) To charge a constant extra premium for the term of policy or a shorter period.

Considering now the first method of limitation of plan, it can be understood that if there were reason to believe that applicants of say 35 would not in all probability experience heavier mortality than good average select lives of this age during the early years of the policy, but that heredity or some personal tendency would cause considerable extra mortality commencing about age 55, there would be justification for offering a 20-year endowment, thereby cutting out all risk to the company after the twenty years.

The second method, the lien plan, is probably in many respects the best method of handling definite substandard risks, either by itself or in combination with a limitation of plan. To show the working of this method imagine an extreme case in which the mortality has been ascertained or anticipated to be double the standard throughout. The risk would be asked to pay the regular premium rate applicable to his age, and in the event of death during the existence of the lien, there would be deducted from the face amount of the policy half of the net sum at risk. To make the case perfectly clear the fact must be borne in mind that the net level premium is built up of two things, (1) the reserve or investment element which year by year accumulates to the reserve, and (2) a mortality element which pays for the year's risk. At the end of a certain period the investment element in a $1,000 policy has accumulated to say $200, and the amount is obviously untouched by the mortality and therefore must be credited in full to the insured's estate, whether he is alive or dead. On the other hand, the mortality element on account of the double mortality will only purchase half the amount it would for a normal life. If an endowment policy were selected or offered together with the lien plan it is evident that on the maturity of the policy the insured would obtain the whole face amount, being thus in no worse case than if he had been the best of risks. He is then in the position of a man who has backed his own vitality and won.

The third method, "rating up" or charging the premium for an advanced age in order to meet the extra risk, has been very popular in Great Britain and Europe. The underlying assumption is that the insured, so long as the rating endures, will be subject to the mortality of a life of the rated-up age. It seems likely that in many cases the extra mortality will not fall according to the manner assumed, so that the method is to that extent illogical.

The fourth method of simply charging an extra premium in cash corresponding to extra mortality for so long as is thought advisable, though it may be made quite a scientific one, has never found great favor with the public.—*Proceedings of the Second Mid-Year Meeting of the Medical Section of the American Life Convention*, February and March, 1912.

The Lien Contract in Substandard Insurance Business.—Henry Wireman Cook, Medical Director, Northwestern National Life Insurance Company, says that he is distinctly in favor of the lien form of substandard business, particularly for the small company. We know that the man who thinks he is going to die soon is most anxious to take a substandard policy of the better class, and if he thinks he is going to live will either not take the policy or will drop it. This is not true of the lien form as it is of the rating-up form, for this reason: A man who does not believe he is going to live will scarcely look with favor on a lien contract, because the limitations of his contract occur during the first few years. If he thinks he is going to die he wants the most insurance he can get for his money, and he will be more in favor of a rated-up contract. The author believes that the enthusiasm about the substandard business is due to the fact that one must recognize the injustice of the average selection of standard and rejected risks. This selection is improper and unscientific. To say that ten men are not insurable and that ninety men are all insurable in some form is absurd. Take one hundred applicants for insurance, properly graded so that they will rate in order from the best risk to the worst risk and no two of these men are equally good risks. Of course it will never become possible to rate them so carefully that each man will have his own separate rating, but as we improve our medical diagnoses we will be able to make more definite decisions regarding risks and rate them according to their probable expectancy. The absurdities of existing methods are obvious. For instance, we call ten per cent. rejected, ninety per cent. standard. In every company from five to fifteen per cent. are borderline cases. One medical director may accept a risk and another may decline it. The personal equation enters in, and this is unfair to the applicant. Every company is taking Bright's disease right along on standard risks.

There is a danger of depending on actuarial experience too closely, without regard to the clinical side of the case. An instance is cited in which ten or twenty per cent. is deducted from a man's rating because he lives in a favorable locality or otherwise. Let it be supposed that a man who lives in Minnesota develops Bright's disease. Minnesota is considered one of the healthiest States in the country. But he goes to Louisiana for his health. In that case we know that he will live longer in Louisiana with Bright's disease than in Minnesota. If you acted in this case from a strictly actuarial point of view, instead of giving the man the benefit of sound medical advice, one would charge him an additional premium. But if he lived in Minnesota, where the cold winters would aggravate the disease, he would get a better rating. Again it has been brought out by Hunter that a man after three attacks of rheumatism should be given a certain definite added percentage, that is, without regard to the clinical side of the case. Let it be supposed that the man's rheumatism is due to diseased tonsils, and that these are removed. Is that man not a better risk after the tonsils have been removed? Most physicians would agree that he should be given a new rating. An injustice can be done the applicant by adhering too strictly to the actuarial point of view, and disregarding the clinical standpoint.—*Second Mid-Year Meeting of the Medical Section of the American Life Convention*, Feb. 28, 1912.

Book Reviews.

Diagnostic Methods: Chemical, Bacteriological, and Microscopical. A Textbook for Students and Practitioners. By Ralph W. Webster, M.D., Ph.D., Assistant Professor of Pharmacological Therapeutics and Instructor in Medicine in Rush Medical College, University of Chicago; Director of Chicago Clinical Laboratory. Second Edition, Revised and Enlarged. With 37 colored plates and 164 other illustrations. Price $4.50. Philadelphia: P. Blakiston's Son & Co., 1912.

The second edition of this unusually valuable book has been enlarged by about forty pages, but by the adoption of thinner paper the actual thickness and weight of the volume have been very advantageously lessened. A careful survey of its pages shows that the revision has been most painstaking, and the reviewer has been unable to detect any omissions worth mentioning. Such recent matters as the methods for the cultivation of *Treponema pallidum*, for performing the luetin reaction, and applying the phenolsulphonephthalein test for renal efficiency are included, as well as whatever else of real importance has been contributed to the field of laboratory diagnosis during the last three years. The discussion of the technique of the Wassermann reaction is especially commendable for its thoroughness and attention to detail. Professor Webster is evidently a very careful student of the literature, and presents excellent summaries of the views of other authors, but at the same time he adds greatly to the interest and value of his text by giving his own opinions freely and stating the conclusions to which his own observations have led him. This suggests mention of what seems to be the one defect of the book—namely, the illustrations. It is really a great pity that a volume of which the text is characterized by so much originality and strong individuality should have so great a proportion of its illustrations taken from other books, and largely from a single one. It is very much to be hoped that these will in the future be replaced by original figures which will put this feature of the book on a parity with the exceptionally excellent letterpress.

A Manual of Surgical Treatment by Sir W. Watson Cheyne, Bart., C.B., D.Sc., LL.D., F.R.C.S., F.R.S., Hon. Surgeon in Ordinary to H. M. the King; Senior Surgeon to King's College Hospital, and F. F. Burghard, M.S. (Lond.), F.R.C.S., Surgeon to King's College Hospital and Senior Surgeon to the Children's Hospital, Paddington Green. New Edition, entirely revised and largely rewritten with the assistance of T. P. Legg, M.S. (Lond.), F.R.C.S. Surgeon to the Royal Free Hospital; Assistant Surgeon to King's College Hospital, and Arthur Edmonds, M.S. (Lond.), F.R.C.S. Surgeon to the Great Northern Central Hospital; Surgeon to Out-Patients, The Children's Hospital, Paddington Green. In Five Volumes, Vol. II. Price $6.00. Philadelphia and New York: Lea & Febiger, 1912.

The successive volumes of this important work are being published with but little delay. This is as it should be, and is a guarantee that the book will be up to date throughout. The present volume contains chapters on: Affections of the skin and subcutaneous tissues, of the nails, of the lymphatics, of fasciæ, of bursæ, of muscles, of tendon sheaths, of tendons, of nerves, of veins and arteries; on the treatment of special aneurysms; fractures; inflammation of bones; necrosis; tuberculous, syphilitic and rheumatic diseases of bones; actinomycosis, rickets, and various disorders of ossification; tumors of bone: and amputations. The two volumes that have now appeared seem to be well up to the high standard of the former edition; and for the practitioner who often wishes for full and detailed information as to the best methods of treatment this work is admirably adapted.

The Classical Psychologists. Selections Illustrating Psychology from Anaxagoras to Wundt. Compiled by Benjamin Rand, Ph.D., Harvard University. Boston, New York, Chicago; Houghton, Mifflin Company, 1912.

This is a book of chief interest to the psychologist and student of psychology; but the general reader will find in it a great deal of material taken from the writings of world renowned psychologists from earliest times. For it is a history of psychology based upon original and translated extracts rather than an ordinary description of systems. It claims to contain the first extant history of the earlier psychological theories. Beginning with Anoxagoras and Democritus, and an introduction from Aristotle's "De Anima," the writer gives selections from the classical psychologists of ancient, mediæval, and modern times, for the most part in chronological order, but with slight variations to permit of grouping according to schools. These selections are sufficiently full and complete to afford an intelligible idea both of author and subject. We may read of the ancient contending sophistic and socratic views in a charming dialogue from that "oldest work in psychology," Plato's Theætetus. Aristotle, the greatest of the ancient psychologists, tells us of the "faculties of the soul"; Zeno, of the Stoics; Epicurus, of those "criteria of truth—the senses, the preconceptions, and the passions"; Lucretius, of "the nature of things," etc. Tertullian, Augustine, Thomas Aquinas, belong to the medieval period. The modern period is introduced with chapters from Thomas Hobbes' "Human Nature," and further comprises selections from the works of Déscartes, Spinoza, Leibnitz, John Locke, Berkeley, Hume, Condillac, Thomas Reid, Herbart, Beneke, Mill, Bain, Herbert Spencer, Johannes Mueller, Fechner, Lange, Wundt, William James and others. Of 726 pages the ancient period takes up 115, the medieval only 31, and the modern period covers 580 pages. Incidentally, it is of interest to find a partial translation of an abstract of the "Analytical Essay upon the Faculties of the Soul," by Charles Bonnet, the Swiss who was an early founder of physiological psychology. While selections from Condillac, Reid, Thomas, Brown, Herbart, Beneke, Mueller and Wundt and some others will also be read with special interest by physicians. The helpful working knowledge of psychology as employed by the psychiater may have to be sought elsewhere. We know of no single volume where so much pertaining to general psychology may be found. It is a fitting companion volume to the writer's "Classical Moralists" and "Modern Classical Philosophers."

A Surgical Treatment of Locomotor Ataxia. By L. N. Denslow, M.D., Fellow New York Academy of Medicine; Late Physician, Diseases of the Skin (Out-Patients). Bellevue Hospital, New York; Late Professor Genitourinary Surgery and Venereal Diseases, St. Paul Medical College, Minnesota. Price 3s. 6d. London: Baillière, Tindall & Cox, 1912.

The so-called Denslow theory that the cord changes in tabes are due primarily to irritation of peripheral nerves, from abnormal conditions in the urethra, was extensively discredited in this country by both neurologists and genitourinary specialists some years ago, when the author practised on this side of the water. Later, a small book was issued in France describing the theory and Denslow treatment; and now the present book appears, in London, claiming the "cure or alleviation" of such symptoms as the pains, ataxia, crises, incontinence, anesthesias, etc., by urethral treatment; and the author states that the disease may at least be held in check by the relief of strictures of the urethra, which he says are always found in every male case of tabes. Tabetics, like epileptics, are notoriously fond of trying any treatment for their condition which they find, in some way, duly advertised. The improvement which they confidently expect is usually not forthcoming, however, and is never commensurate with the alteration of the pocketbook which is a *sine qua non* of most of the sure cures.

Recent Advances in Hematology. Being the Dr. James Watson Lectures for 1910. By Walter K. Hunter, M.D., D.Sc., Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow; Physician to the Glasgow Royal Infirmary; Extra Physician to the Royal Hospital for Sick Children; Lecturer and Examiner in Practice of Medicine, Glasgow University. With a colored plate. Price $2.25. New York: William Wood & Company, 1912.

Despite the energy which has been applied to the study of hematology in the last fifteen or twenty years, there are still many disputed points and the classification of many of the diseases of the blood is as yet on no very firm foundation. It is difficult, therefore, for a beginner to wade through the enormous literature on the subject which has accumulated, and to obtain any clear impression of our present views on the blood. Especially is this true with regard to the German school which is now apparently engaged in an endless polemic on minor details of morphology, a procedure which is not likely to add much to our knowledge. A short and clear statement of facts and current theories has long been needed, and this little volume of Hunter's supplies the want most perfectly. It is quite full on what we know and fortunately leaves the discussion of what we do not know to other more voluminous texts. As a review of present opinions on the blood it is perhaps the most useful book of its size and scope which has come under the reviewer's notice.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Annual Meeting, Held in Liverpool, July 23-26, 1912.

(*Continued from page 274.*)

SECTION ON OBSTETRICS AND GYNECOLOGY.

First Day—Wednesday, July 24.

PROFESSOR BRIGGS OF LIVERPOOL, IN THE CHAIR.

The Results of Treatment of the Inflammatory Diseases of the Uterine Appendages.—Dr. W. S. A. GRIFFITH of London opened a discussion on this subject, taking the medical aspect. He said that the treatment of these diseases had passed from simple methods to operative surgery with in many cases great benefit. In recent years, by means of bacteriology, the causes were being discovered and in consequence medical treatment was coming back with results more promising than in the past. It began with prevention and he thought that more should be done in the instruction of men with gleet. The best step was the arrest of the infective process in the vulva and vagina whenever possible, and the third was the use of sera and vaccines. The older writers, as Matthews Duncan, never operated, and even in cases of pelvic abscess were reluctant to interfere; the advance of surgical treatment had led to more exact pathological knowledge. The old treatment included rest in bed, aperients and depletion by leeches to the cervix, compresses, opiates and, later, mercurial ointments and blisters. Many of these means were still useful. Thermal treatment now consisted in poultice and hot douches; he had had good results from the continuous hot douche. Radium had been tried in France and good results had been reported. Serums and vaccines had been much used and much improvement in their use had followed more careful bacteriological investigations, but there were many difficulties. Acute vaginitis was not always of gonorrhea origin. Gonorrheal vaginitis could usually be cured in two to three weeks by local treatment, and he laid stress on the importance of vaginal disinfection in cases of abortion. The uterus could be disinfected by the flushing curette with subsequent swobbiing with antiseptics, and he had had good results from this, even when the tubes were involved. Nearly all the infections of the tube were ascending, except that of tubercle. Serums must be used early to do any good and he had found vaccines most useful in preventing extension of an infection and that they acted like disinfection of the vulva and vagina. The value of the latter could not be over-estimated; he used iodine. Vaccines had given good results in the valvovaginitis of children.

Mr. CHRISTOPHER MARTIN of Birmingham spoke from the surgical aspect. He said that he did not resort to operation until he had made a good trial of medical means. In the past many mutilating operations had been needlessly performed. Dealing firstly with ovarian inflammation: Acute ovaritis rarely called for surgical treatment and it would be as reasonable to remove a testicle for orchitis. If an ovary can be felt as a bag of matter an incision in the posterior fornis was called for and removal could be done more safely later. The more severe the local lesion the better were the results from operation. No good resulted from oophorectomy in the chronic neurotic. The remote results of the removal of both ovaries were indefinite. Menstruation ceased. The whole genital canal underwent atrophy. There was a tendency to the formation of caruncle and patches of vascular degeneration. Severe vaso-motor changes. None of the above changes occurred if even a small piece of ovary was left behind. When they did occur they could be removed to some extent by administering ovarian substance of the sheep.

Tubal inflammations were due to gonorrhea, tubercle, sepsis, and the infection spread directly from the uterus. In most cases adhesions formed. Many cases of a chronic character could be treated by conservative measures, opening up ostium and performing, curetting, and ventral fixation. Many cases of salpyngitis were due to previous appendicitis, and in operating the appendix should always be examined. In unilateral salpyngitis he would not remove both tubes, but would curette the uterus when the diseased tube was removed. In bilateral disease he would remove both tubes and the uterus, saving part of an ovary if possible. In acute pyosalpyns he advocated vaginal incision, doing an abdominal section later if necessary; in these cases primary abdominal section was full of danger. The sequelæ of these operations were: hernia; this was less common, since abdominal drainage had been done less frequently.

Sinuses may be due to foci of infection which had been left behind, or to silk ligatures; he now used catgut only.

Fecal fistula. This was most common in tuberculous cases; menorrhagia, occasionally, when uterus was not removed.

Dr. HAULTAIN of Edinburgh had seen good results in some cases after removing the ovaries for epilepsy when the latter appeared to be distinctly menstrual in origin.

Dr. SCHARLIEB of London said that results were much better since the introduction of vaginal drainage. She agreed with removal of the uterus in many cases, but she always tried to keep a portion of an ovary; she considered that some of these operations were the most difficult in gynecology.

Dr. ARMAND ROUTH of London advocatd antiseptic treatment of the uterus and vagina; he applied iodine (1 in 4) to the endometrium. He had found electric light and heat both very useful. He insisted on the importance of physiological rest for the organs for many months after treatment had ceased, and the husband should be examined to prevent re-infection. He had found vaccine treatment, using doses of 10,000,000 gonococci, do much good. In acute cases he advised waiting for the condition to quiet down and the pus to become sterile before operating. Spontaneous rupture of pus tubes was very rare. He also approved of vaginal incision in acute cases, doing an abdominal section later if necessary.

Sir JOHN BYERS of Belfast had had good results from vaccines, but had not found serum beneficial. He also urged preventive measures, antiseptics in labor, and instruction in regard to gonorrhea. He did not believe that gonorrhea ever caused acute puerperal sepsis.

Professor HELLIER of Leeds said that some patients cannot afford time for medical treatment; he had found yeast suppositories very useful in acute gonorrhea.

Dr. BECKWITH WHITEHOUSE of Birmingham had made bacteriological investigations which showed that in many cases of salpyngitis the uterus was sterile.

Dr. PURSLOW of Birmingham said that in his experience the gonorrheal cases showed much greater tendency to spontaneous recovery than those due to other injections.

Dr. FRED EDGE of Birmingham said that pus tubes were sometimes due to gonorrhea at the uterine end of the tube. He said that there was much liability to recurrence in the tube which was apparently healthy at the operation. The danger of vaginal opening was the risk of mixed infection.

Dr. BELL of Bradford had tried vaccines in gonorrhea in both males and females and had found little benefit. He placed great faith in nature's power of cure.

Dr. FRANCES IVENS of Liverpool combined vaccine treatment with surgical measures; treated cases by abdominal section without drainage when due to gonorrhea.

Dr. GEMMELL of Liverpool had found that gonorrheal cases recovered spontaneously better than septic cases. He had experienced no success in the treatment of sterility by opening up occluded tubes.

Professor BRIGGS of Liverpool said that the drainage was more free by the vaginal than the abdominal route and he advocated the former. He had seen benefit from vaccines in cases associated with gonorrheal rheumatism.

Dr. GRIFFITH, in reply, said that if one drug was useful in chronic inflammatory affections that drug was mercury. He considered it unjustifiable and harmful to remove ovaries for epilepsy. Conservative treatment was not advisable in tuberculous cases.

Dr. CHRISTOPHER MARTIN, in reply, also disapproved of operating in epileptic cases; said that the late Professor Taylor had pointed out that chronic cases could be cured by prolonged course of mercury and iodide, and he agreed with this.

SECTION OF SURGERY.

First Day—Wednesday, July 24.

The Treatment of Carcinoma of the Rectum.—Dr. HARRISON CRIPPS of London opened the discussion. He first glanced briefly at the modern history of the subject in connection with the names of Lisfranc, Dieffenbach, Marchant, Kraske, Kelsey, Paget, Jersof, Allingham, Edwards, Mummery, and Handley. The bearing of pathology on surgical treatment was then noticed. The growth is almost invariably in the form of adenoid cancer growing from the base of Lieberkuhn's follicles into the submucous and other coats of the rectum, thence to lymphatic glands and the liver and other organs. In structure rectal cancer is very like an innocent papilloma; but the latter grows into the lumen by branches, whereas the former grows

downward by roots. He saw no evidence that mechanical irritation will produce a cancer of the rectum, and thought a specific organism bringing infection from without the body would in time be discovered. He likened the process to gall-tumor promotion in the oak due to the irritation of the egg of *sineps quercus folii*. Rectal cancer is always local in origin, and at first tends to spread horizontally rather than deeply. Ulceration ensues with a hard edge, ending abruptly in sound mucous membrane. Lymphatic infection was a late stage, and thus rendered operation more hopeful. He objected to Mr. Handley's view that rectal cancer cells permeate the lymphatics some inches beyond the original site without producing hardness of the tissue, with the inference that long lengths of bowel should be excised to prevent recurrence. Clinical experience is opposed to this deduction, for resection at a line an inch or less from the apparent limit of disease is seldom followed by recurrence except at the extreme edge of the cut margin; and even this is exceptional, because as a rule cancer reappears in structures external to the bowel. He regarded one inch as a fair margin, and could cite dozens of successful cases where no more had been allowed. A valuable procedure would fall into discredit if wholesale removal was practised in deference to an unproved pathological theory.

Turning to diagnosis he held that certainty was only possible by digital examination. A hard surface must be actually touched by the finger. If within six inches of the anus this is easy. The utmost gentleness must be used or the gut might tear like wet paper. The sigmoidoscope is worse than useless for diagnosing rectal cancer.

In selecting cases for operation regard must be had to the prospect of removing the whole disease. He has not been able to recommend excision in more than one-third of his cases. Contraindications are: (1) Obvious dissemination in internal organs; (2) inability to define the upper edge if the sacral route is contemplated, or to push the growth upward for an abdominal operation; (3) fixity to neighboring parts. Age, of itself, is not of much importance, as old people will stand well a moderate operation on the rectum. If excision is impossible, colotomy in suitable cases robs the disease of its worst symptoms, and often prolongs life in a tolerable form. Excision may be done from below or from above, and there is no sort of rivalry between the two methods, the choice being settled on the merits of each case. He described the sacro-perineal operation in detail, including the after treatment. Finally he submitted an analysis of 445 consecutive cases of rectal cancer occurring in his private practice. Colotomy was performed in 151 cases and excision in 108; of the latter 100 recovered. Five of the operations were by the abdominal route, two of them fatal. Of the 100 successful cases of excision 42 remained well for three years and upward. Where colotomy was done the average duration of life was 22 months. He summed up the deductions to be drawn from his experience as follows: (1) That cancer of the rectum may occur at any age, but chiefly after middle life. (2) The disease is twice as frequent in men as it is in women. (3) The importance of early diagnosis, for two-thirds of the cases were too late to admit of excision. (4) That when removal was practicable nearly 40 per cent of the cases were curable. (5) That if recurrence takes place it almost invariably shows itself within twelve months. (6) That colotomy prolongs life.

Dr. G. Heaton of Birmingham found not less than 25 per cent of hospital patients with rectal cancer came for treatment soon enough to make a radical operation possible. The chief contraindications to a complete operation were (1) implication of urethra, prostate or bladder, (2) metastasis in iliac gland, viscera, or peritoneum. Inguinal colotomy was a great boon in inoperable cases; it not only lessened pain and prevented obstruction, but also checked the rate of growth of the cancer. In regard to excision every other consideration must give way to thorough removal of the growth and its lyphatic area. A preliminary colotomy 8 or 10 days before the major operation is advisable; through the abdominal wound the extent of the disease can be determined and information gleaned as to metastases; diversion of feces from the rectum left the field of operation cleaner and healthier; the diseased gut can be removed without opening it; the miseries arising from the incontinence of a sacral anus, or from a strictured rectum, are avoided.

Dr. Sinclair White of Sheffield said his hospital cases of excision of cancerous rectum showed a mortality of about 30 per cent in a series of 78 operations, mostly of the transsacral type. His private cases were more successful, the mortality being 18.7 per cent in 32 operations, of which 29 were by Kraske's method and 3 abdomino-perineal. No case was rejected unless the growth was fixed to the bladder or prostate, or there were metastases elsewhere. In the Kraske group his rule was to perform an iliac colostomy 10 to 14 days previous to excision, and when feasible he preserved the lower end of the rectum with its sphincter. In 6 of the 29 cases a sacral anus resulted. The endeavor to restore the rectal tube with its sphincter accounted for a large percentage of local recurrence of cancer. This method should be restricted to cases where the growth is small, movable, and not lower than three inches from the anus. For less favorable cases free excision must suffice, and this is best done by Hochenegg's method. The abdomino-perineal operation is ideal in conception, but the mortality is very high, especially in males, owing to the depth and narrowness of the pelvis. In his three cases two were females who both did well; the third, who was a male, died of peritonitis. Viewing rectal cancer as a highly malignant disease, more so than cancer of the colon or stomach, free removal was necessary in order to avoid recurrence, incomplete removal being worse than useless. The primary aim should not be an ideal plastic result, but radical extirpation of the growth. An iliac artificial anus with a proper appliance did not bar a patient from useful work, as was instanced by the case cited of a tramcar conductor employed in a large city.

Dr. Sampson Handley of London claimed that clinical evidence supported his view of the permeation of cancer cells. He had found cells extending more than four inches from the growing edge in rectal cancer, and he quoted Swinford Edwards' observation that in 50 per cent. of the cases of perineal excision recurrence appeared in the cut edge of bowel. He advocated the combined radical operation, though he admitted that the present mortality rate of 20 per cent. was too high to give the procedure a permanent position in surgery; but the mortality would diminish as the technique improved. He agreed that it was an objection to the combined method that end-to-end anastonosis was unattainable; but the advocates of the perineal operation were bound to admit that this ideal result could only be achieved in an extremely low proportion of their cases.

Dr. C. P. Childe of Portsmouth urged the advantage of the sacral route for excision. He preferred to operate in two stages, first making an inguinal anus and excising the disease fourteen days later.

Dr. Leedham-Green of Birmingham thought the mortality of the combined operation would compare favorably with that of the sacroperineal. He operated in two stages, first opening the abdomen, sewing the omentum to the posterior surface of the abdominal cavity low down so as to make a partition below the small intestines, and then dividing the rectum above the disease and forming an inguinal anus. In the second stage a fortnight later he again opened the abdomen and completed the excision.

Dr. H. Paterson of London supported the views of Dr. Cripps; and agreed that when the disease was too extensive for removal from below, with very rare exceptions, it should be left alone. Explanation of the liver through a small incision would fail to discover metastases in 50 per cent. of the cases, and was therefore of very little value. If Dr. Handley's view of widespread fermentation is correct then it must be assumed on clinical facts that nature is able to dispose of the outlying cancer cells.

Dr. A. Don of Dundee advocated the combined operation, and thought the sacral route would in time be abandoned. He advised a free abdominal incision for preliminary exploration, and ligature of the internal iliac arteries before cleaning out the pelvic colon.

Dr. Jordan Lloyd of Birmingham was opposed to the extensive procedures recently introduced. In his experience the majority of cases met with were best left alone, palliative measures being adopted. He drew attenion to two main types of rectal cancer—one, in which the growth formed a local lump, being ill-suited for operation; the other, in which the growth took a tubular form, being much more favorable.

Dr. Armstrong of Montreal was in favor of the combined operation in two stages with an interval of fourteen days. His practice was to make an inguinal anus, and not to attempt end-to-end junction of the divided bowel.

Dr. Hey Groves of Bristol insisted on the value of exploration to search for secondary growths in the abdomen, and he agreed that end-to-end junction was too risky a procedure in general. He practised the two-stage operation, not opening the abdomen in the second stage but removing the diseased bowel from below.

Prof. Cameron of Toronto associated himself with those speakers who protested against very extensive resections on the ground that the mortality was prohibitive.

D. A. Fullerton of Belfast did not agree with Dr. Cripps that the sigmoidoscope was useless in the diagnosis of rectal cancer. He cited two cases of excision by the posterior route followed by good functional control. In each case the coccyx was removed. An attempt to join the cut ends of the rectum in one case failed, but a channel was maintained by a Paul's tube, and after a few weeks the posterior wound healed. In the second case he divided the superior hemorrhoidal artery well away from the bowel and brought the pevic colon down to the anal canal, which had been bared of mucous membrane.

Dr. G. P. Newbolt of Liverpool much preferred the posterior operation, and found that excision of the coccyx alone gave adequate access in the majority of cases that could be deemed operable. He cited two cases in which end-to-end junction became feasible after a few months owing to prolapse of the bowel through the sacral anus.

Second Day—Thursday, July 25.

The Diagnosis and Treatment of Tuberculous Disease of the Urinary Tract.—Mr. Harry Fenwick of London opened the discussion on this subject. He said the bedrock fact of renal tuberculosis was that the kidney excreted bacteria and toxins, and these passing down the ureter gave rise to symptoms which simulated cystitis, so that the disease when first noticed by the patient was referred to the bladder. He suggested that discussion should be directed to the questions: Is the kidney the starting point of urinary tuberculosis? and is surgery the only means of cure? In his experience the disease was never primary in the female bladder, but in males infection was frequently traceable to a genital origin. Another difference between the sexes was brought out in the statistics of 1,000 cases submitted to the congresses which had been held in Vienna and Rome, namely, that the results of operative interference were far less satisfactory in males, and there was a much greater tendency in males to chronic lung trouble and generalized tuberculosis. The aid of the bacteriologist is invaluable in diagnosis. If tubercle bacilli are found in the urine of women suffering from symptoms suggestive of cystitis, renal tuberculosis is to be presumed. A thickened ureter resembling a slate pencil crossing the base of the bladder may be palpated in some cases on examination per vaginam or per rectum, and this indicated advanced disease in the corresponding kidney. Such a ureter presents a funnel-shaped meatus on cystiscopy. The orifice of the ureter in vente descending ureteritis is surrounded by a group of small globular swellings which appear like bubbles; and as this condition is not favorable for nephrectomy, operation must be postponed. In about 8 per cent. of the cases of tuberculous kidney the ureteral orifice appears normal on cystoscopy. Drawings were exhibited showing the appearances of kidney and meatus of ureter at different stages of disease. With regard to treatment, tuberculin is a powerful tonic, but not curative; it should only be given when the ureter is an unblocked channel through which the renal excretion can escape; exceptionally it is justifiable to give it in a large dose as a diagnostic by reason of the painful reaction it set up in a tuberculous kidney. Given a sound organ on the other side, a radical cure is effected by nephrectomy. To avoid contamination of the wound the kidney should not be opened on exposure, the diagnosis having been established before operating. A thickened ureter need not be traced low down; it should be curetted for 2 inches and it required no ligature. In order to secure primary healing of the wound drainage should not be employed as a rule. With regard to the tuberculous bladder, the less it was touched the better; as a secondary disease its tendency was to heal on removal of the kidney. When seen in a late stage with its capacity reduced to a dram or two, the state of a patient is one of misery which can only be relieved by short-circuiting the ureters through the loin. The speaker cited the following cure: A girl at 18, with symptoms of cystitis for 2 years and whose urine contained tubercle bacilli, appeared to recover after treatment with tuberculin; 18 years later she again came under observation, her bladder then holding 2 drams; a radiograph showed a large obsolete right kidney, and on cystoscopy the site of the right ureteral orifice was found occupied by scar tissue, while the left one appeared normal. The right kidney was removed and the left ureter short-circuited through the loin, recovery followed and the patient survived a year.

Mr. Fullerton of Belfast referred to tubercle of the bladder. This disease is frequent in Ireland, a series of 700 cystoscopies showing 56 cases of tubercle of the bladder, the sexes being equally divided. The most frequent age incidence was between 20 and 30. Tubercle bacilli were found in 37 of the 56 cases. The symptoms were mainly those of cystitis, renal pain being of late occurrence as a rule. Too much reliance must not be placed on enlargement of the kidney or thickening of the ureter, for these signs may belong to the only functional kidney present. He thought tubercle of the bladder might sometimes be primary. In 50 of the 56 cases it was secondary to renal tuberculosis and in 4 the primary disease was in the epididymis and prostate. In most cases the disease appears to be unilateral. Cystoscopy is of very great value in ascertaining which kidney is at fault, supplemented by the ureteral catheter. The slight risk of such instrumentation is justifiable in view of the indispensable knowledge thereby gained. In his 17 nephrectomies for tuberculous kidney there were 2 deaths.

Mr. E. Deanesly of Wolverhampton agreed that urinary tuberculosis was more amenable to surgical treatment in women than in men; the mortality after nephrectomy was lower and there was a less tendency to infection of other organs. He advocated cystoscopy in every case where the disease was suspected and said that the ureter and trigone showed only insignificant changes in the early stage. Ulceration of the ureteral meatus is not peculiar to tubercle, as he had seen it in a case of renal calculus. He thought the ureteral catheter gave valuable help in diagnosis, but its use was not free from risk. With regard to treatment, in his opinion nephrectomy was the best means available if the other kidney was healthy. His practice is to expose both kidneys through the loin, the patient being in the prone position; by this procedure the condition of the other kidney can be ascertained before the nephrectomy is completed without moving the patient. Tuberculin is of service in the after treatment as a remedy for curing ulceration of the bladder.

Dr. White of Sheffield instanced 6 cases of ureteral calculus preceding tuberculosis. As tubercle was often present in other viscera he deprecated too zealous operative interference, and held that expectant treatment on judicious lines gave encouraging results, nephrectomy being reserved for selected cases. In long-standing disease the kidney may become blended with the duodenum or veva cova.

Mr. Temple Mursell of Johannesberg said the open-air treatment on expectant lines in South Africa failed to cure renal tuberculosis. The effectual remedy for the disease was nephrectomy.

Dr. Darling of Lurgan mentioned a case in which the prostate right ureter and kidney were tuberculous 11 years ago and tuberculin was then given in conjunction with open-air treatment. Marked improvement followed, but a year ago the patient's health broke down under recurrent pyrexial attacks. Six months ago coliform bacilli were detected in the urine; treatment with a suitable anti-vaccine was then undertaken and the patient is now practically well.

Mr. Childe of Portsmouth said that drawings of the nephrectomy wound should be omitted if possible, because there was a danger of the track becoming infected with tubercle.

Mr. Fenwick in his reply objected to the simultaneous exposure of both kidneys; inspection of the surface was often fallacious, and the functional activity of both organs should be determined before operating.

Transarticular Operation for Fractures Near the Knee and Elbow.—Mr. Sampson Handley of London read a paper on this subject. The operation he proposed was to be reserved for special cases of fracture near or extending into the joint, due precautions being taken against sepsis. He narrated two cases. (1) A boy at 9, with separation of the lower epiphysis of the left femur flexion and a figure-of-eight bandage was tried, but a radiograph showed persisting deformity. Another surgeon advised excision of the joint. The author operated as follows: The fragments were exposed through an anterior U-shaped flap turned upward with the potella and fixed accurately by two screws, one passing through each canople; all the ligamentus structures divided were reunited by sutures; the lateral ligaments were preserved intact. The patient was discharged in 7 weeks and at the end of 3 months the bone and joint were perfect. (2) A boy at 12 with backward displacement of the lower epiphysis of humerus which could not be reduced under anesthesia. A transarticular U-shaped flap, clear of the ulvar nerve, was turned up over the back of the elbow joint, and the olecranon divided at its base; the fragments were easily placed in correct position and no screw was needed to keep them adjusted; the olecranon was sutured with silk, and the soft parts were also sutured. The result was very satisfactory, and it was claimed that the operation averted the alternative of excision.

Mr. H. A. Ballance of Norwich held that separation

of the lower humeral epiphysis is very rare, and that fractures into the elbow joint are less frequent than supracanoplar fracture. In children all fractures of the lower end of humerus require operation, other forms of treatment resulting in an alternation of the "carrying angle." In his opinion the best incision is a vertical one over the back of the joint, and division of the olecranon is quite unnecessary. If the case is dealt with within 48 hours the fragments can be replaced without mechanical supports; beyond that interval one or possibly two screws may be required. He has entirely given up the non-operative treatment of the fractures under consideration.

Prof. Rushton Parker, president of the Section, advocated the treatment of lower humeral fractures by acute flexion of the elbow. The limit should be maintained in that position under the clothes for several weeks, and active movements then persevered with. The result of this treatment is an efficient joint with a good range of mobility, even though the bones are not in a perfectly correct position.

Complete Excision of the Hemorrhoidal Area.—Mr. A. Dorr of Dundee described the operation he practised and gave the results in 50 cases. The precudure is a bloodless modification of Whitehead's operation, claimed by the author to be less liable to leave insensitive and contracting scar tissue. The sphincter is dilated but not torn, and a cork on a corkscrew inserted just beyond the bluish pile area; below the cork a ring of pink mucous membrane is grasped by six pairs of Kocher's forceps and the cork is then drawn down to the tips of the forceps; the handles are gathered round the corkscrew and several harelip pins inserted; each pin is put in between two of the forceps, entering at the junction of skin and mucous membrane, and passes in front of the sphincter until it pierces the cork behind the ring of pink mucous membrane; a piece of elastic is wound twice round the pins, and the ends held below with forceps; the Kocher's forceps and corkscrew are now removed, the surface of the pile area cleaned and all the mucous membrane dissected off the sphincter between the white border line below the pink margin above, no hemmorrhage taking place at this stage; a continuous button-hole suture of chromic catgut is next inserted all round, thus bringing skin and mucous membrane into exact opposition; the elastic band is now removed and if one or two bleeding points appear they are controlled by mattress sutures put in through the skin till the needle reaches the cork and out again at a point ½ inch away, and ¼ inch behind the primary suture; finally the pins and cork are removed, a gauze roll introduced as a plug for a few hours and morphine given *sub cute*. The author summarized the end-results and said they were superior to those gained by other operations for the cure of hemorrhoid.

Obstruction of the Ureter Due to (1) Kinking Over a Branch of the Renal Artery; (2) Renal Calculus.—Mr. R. A. Bickersteth of Liverpool read this paper and exhibited specimens and drawings which illustrated the different effects produced in the kidney and its pelvis by the above-stated causes of obstruction.

SECTION ON MEDICINE.

First Day—Wednesday, July 24.

Early Cardiac Complications of Acute Rheumatism.—Dr. David Lees said he had long held rather decided views on the subject, some of which are not generally accepted though they seem to attract attention by those who have good opportunities of submitting them to clinical observation. He began by saying that rheumatism, both acute and subacute, is to be regarded as a microbic infection. It is most frequent and most violent in childhood, diminishing in both respects as growth proceeds, but still remains a grave disease in adult life. He holds that dilatation of the left ventrical is always present, and is doubtless caused by myocarditis and toxemia. One of these may suffice, but both are mostly combined. Perhaps one may depend on the other. The dilatation is a very early symptom, invariably present, and can practically be easily detected on careful percussion properly carried out. It is easy to determine quite accurately the sloping line of dullness at the edge of the left ventricle in the fourth and fifth left interspaces and that of the right auricle in the right fourth interspace. Apart from the ventricular dilatation Dr. Lees seemed to attach little importance to other symptoms. Joint trouble, nodules, endo- and pericarditis, and pleuritis were not constant symptoms, as each or even all might be absent in some cases, but the dilatation was always found. As to treatment, prolonged rest under careful nursing takes the first place. An ice-bag over the precardia (with precautions against chill) was also spoken well of and a few leeches were mentioned as sometimes beneficial. But Dr. Lees also believed in active medication, salicylates and alkalies in full doses keeping the bowels regularly open and the urine alkaline. His favorite combination was sodium salicylate 1 part to sodium bicarbonate 2 parts, the dose of this to be regularly increased as long as it is tolerated. If it produces vomiting or other toxic symptoms due to the salicylate it must, of course, be suspended to permit recovery from these effects. After this it should again be given in half the dose at which it had to be stopped and this should be increased as far as possible.

Dr. Abrams of San Francisco accepted the treatment by salicylates as essential and was of the opinion that ventricular dilatation was as frequent a complication of rheumatism as had been stated. But essential as it is to get the full influence of the salicylate he had come to regard it as possible that the drug itself might be capable of setting up ventricular dilatation. He referred to the importance of the vagus in reference to the cardiac symptoms, for which he held the salicylates were useless. Pilocarpine was valuable in heart failure.

Dr. Poynton could not accept the constancy of ventricular dilatation nor yet the utility of the salicylates. Perhaps the drug might be effectual in some cases, but not in others. Bacterial poisons were soluble and varied with the tissues concerned. Mitral stenosis in recurrent chorea was common and other cases indicated that the cardiac complications of acute rheumatism began with tachycardia.

Dr. Carey Coombs, from recent experiments on rabbits made in conjunction with Dr. R. Miller and Dr. Kettle, concluded that streptococcal infection was the cause and histological examination showed similar lesions whatever were the organs attacked. They had seen no differences from five different strains of streptococci. The type of reaction was like that of human rheumatism.

Dr. Frederick Langmead said that out of 2,556 London school children he found rheumatism in 5 to 6 per cent.; it was commonly undetected in a first attack, therefore not treated, and resulted in a crippled heart developing insidiously. Large tonsils required operation four times as often in rheumatic as in normal children, suggesting that those observers were correct who considered them a probable source of infection. He thought a crusade was required against rheumatism.

Dr. F. W. Price spoke of early diagnosis and preventive measures as the most hopeful fields of study.

Dr. Wm. Hunter urged that treatment should be influenced less by the symptoms or clinical course of the disease than by its cause and the source of infection in each case.

(To be continued.)

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held May 20, 1912.

The President, Dr. Reynold Webb Wilcox, in the Chair.

X-Ray Measurement of the Permanent Teeth Before Eruption, to Provide for Early Regulation of the Dental Arch.—Dr. Sinclair Tousey, in this paper, said that in 1906, when his first work in this connection was undertaken, he had shown, at a meeting of the New York Institute of Stomatology, a series of radiographs of the unerupted permanent central incisors, with a promise to complete his report after these teeth had erupted. A certain number of the children had now been traced, and the actual measurements compared with those predicted by the *x*-ray. The practicability of radiographing the teeth of children five or six years of age was shown by his series of cases, now amounting to over thirty, while its desirability was shown by the number of children whose permanent teeth came in crowded and out of alignment or, through malposition, were delayed in eruption. In some instances some of them were altogether missing. Actual measurement of the temporary teeth would give no information as to absence or malposition of the unerupted permanent teeth, and his cases showed that actual measurements of the temporary teeth do not correspond with the actual measurements of the permanent teeth made after their eruption. The most important measurement was the greatest width, in hundredths of an inch, of the unerupted central incisors; the upper ones being of chief consequence. Mathematically exact measurements would require a geometrical calculation, since the unerupted tooth was at a certain distance from the film, and consequently its shadow was slightly enlarged. This calculation showed

that about 1/30 of the width of the shadow of the unerupted tooth should be deducted to obtain the actual width of the tooth in a radiograph made upon a horizontal film according to his present technique. Another detail requiring close attention was in the measurement of the width of the shadow, so as not to include the penumbra. The direction of the tooth casting the shadow was a matter of vital importance, a correct radiographic measurement being possible only when the tooth directly faced the *x*-ray tube. The tooth whose occlusal edge was squarely at a right angle with its long axis in the radiograph was the one to be depended upon for a correct measurement. This was one of the special advantages of his method of casting the shadow of the teeth upon a film placed horizontally in the mouth. The curve of the dental arch was shown, and it was easy to see whether a tooth directly faced the *x*-ray tube and at what angles the others were placed. In some instances the radiograph showed that both unerupted centrals were turned so far to the sides that an exact measurement required another radiograph with the tube sufficiently to one side. This revelation of the sharp angle between the centrals was important, as indicating narrowness of the dental arch. It was his practice to make accurate measurements of the width of each temporary upper and lower central when making the radiographs of the unerupted permanent centrals. Knowing the actual measurement of the temporary teeth, and applying the caliper square to the *x*-ray image of the same teeth, one soon became able to measure the latter accurately. Dr. Tousey had made many hundred radiographs in older children and adults to determine the presence or absence and the position of unerupted teeth which had caused years of uncertainty. This would all be obviated, he said, by an *x*-ray examination at about the age of six years. As to how nearly accurate these measurements were likely to be, in none of his cases did the difference between the radiograph of the unerupted tooth and the actual width of the same tooth measured after eruption, some years later, exceed 1/100 inch, a variation which was well within the accuracy required for practical work in orthodontia. In the majority of instances the radiographic measurement of the unerupted teeth was just the same as the actual measurement of the erupted ones. His series of cases had shown that there is no fixed relation between the width of the temporary teeth and that of the permanent teeth. In speaking of the practical application of the method he said that the upper arch was the one which it seemed most important to determine, and it was practicable to measure the widths of not only the central incisors, but also of laterals and canines. The cases so far examined showed that an arch calculated from the width of the upper central permanent incisor was the correct one for the purpose desired. The curve of the temporary arch, whether right or wrong, was reproduced in the permanent arch. Imperfect development of the teeth was not only a disfigurement, but rendered proper mastication impossible and the proper action of the saliva unlikely. The effects were starchy indigestion and irritation from unmasticated meat, with autointoxication from both. In the young child the nasal passages were lined below, in front, and on both sides by the germs of the teeth, and imperfect development of the teeth and maxillary bones supporting them occasioned mal-development in the bony walls of the nasal passages and the accessory pneumatic sinuses of the face; while the effect of the under-development might even extend to the cranial cavity and the brain. Deviation of the septum and mouth-breathing unrelieved by the removal of adenoids and tonsils were among the results of mal-development of the teeth. The object of his most recent work had been to determine beforehand the presence and position, and especially the size of the permanent teeth before the loss of the temporary teeth. The latter might be quickly and easily trained to a curve of the proper radius, and would then guide the permanent teeth into proper position. This work showed the size which the permanent teeth would have and the radius of the curve required to accommodate them.

The paper was illustrated with lantern slides showing radiographs and tables of cases.

Wheat Bran in Constipation.—Dr. A. Ernest Gallant, after describing the structure of the wheat grain, said that in the process of converting wheat into flour it was ground on five or six different rolls and passed through sieves until the bran was eliminated. The purposes which bread or any other food served when taken into the body had sometimes been compared to the use of fuel in a steam engine, but while food was the fuel which furnished the energy for all the body activities, as coal supplied the heat to make the steam to drive the engine, it did much more than this: also building the body engine and keeping it in repair. The comparatively small amount of digestible protein and available energy in the feces from bread made with patent flour (that commonly in use), as compared with the entire wheat and graham flour, was no doubt due to the fact that the patent flour was much more finely ground. Experiments on animals had shown that fineness of division of the particles had a material influence upon the digestibility of a food. While it was sometimes claimed that raw foods possessed special virtues because some vital principle or life force in them had not been destroyed by cooking, this was not supported by experimental evidence; nor did physiological chemistry offer any data warranting such a view. On the other hand, there was no reason to suppose that uncooked cereal foods were unwholesome if clean and free from bacteria, while they were commonly said to be especially useful in counteracting constipation, on account of the large amount of indigestible crude fiber which they supplied. When compared with patent flour, bran showed .56 per cent. less water, 9.82 per cent. less carbohydrate, 2.03 per cent. more protein, 2.78 per cent. more fat, and over sixteen times as much ash, composed chiefly of potassium phosphate, calcium and magnesium chlorides, and phytinic acid compounds. The digestibility and nutritive value of the iron compounds met with in the outer layers of the grains probably depended largely upon the fineness of the grinding employed. Experiments made by Bunge upon rats indicated that the iron of bran was assimilated by the body and promoted the formation of hemoglobin. The laxative properties of bran had long been recognized in the very general use of bran mash to correct a tendency to constipation in farm animals, and some recent experiments at the New York Experiment Station indicated that this laxative action was due to a soluble phosphorus compound known as phytin, which occurred in considerable amounts in bran. Such action was the more readily understood when it was remembered that the channel of secretion of phosphorus, calcium and magnesium especially, and a part of the potassium supplied in bran, was by way of the intestine. While no one who had fed animals their weekly or semi-weekly bran mash would question the laxative properties of this, Dr. Gallant said he was thoroughly convinced that for the relief of habitual constipation it must be taken daily in relatively small doses, and that when so used one must depend upon the coarse, unground bran, the bulk of which added very materially to the amount of feces. Thus it excited more vigorous and efficient peristalsis and promoted a regular daily evacuation of the bowel. This would take place only by close, habitual and prompt response to the earliest inclination, for if such were neglected the contents of the rectum would rapidly become firm and compact, and more or less difficulty would be experienced before it could be emptied. Therefore, to secure the good effects of habitual daily use of bran it was necessary to give close attention to the habitual daily stool. Coarse raw bran, being composed chiefly of indigestible, non-absorbable cellulose, took up a large amount of water, swelled, and added very materially to the débris and bulk in the intestine, and the active peristalsis excited by this means rapidly moved the fecal column downward and outward; thereby overcoming fecal stasis and preventing putrefaction and resorption with its deadly toxemia. When bran was ingested as a part of the daily regimen of a constipated individual the daily stool was made up of a soft, well-formed, bulky column of feces with a notable absence of the former foul-smelling effluvia. As time went on the "liver-spotted" skin cleared up, dandruff of indigestion disappeared, the anemia present rapidly improved, the cutaneous surface lost its dryness and became soft and of a healthier hue, and in some instances acne vulgaris passed away. In the experience of the speaker, the best results had been obtained by the use of coarse, unground raw bran, either stirred in a glassful of cold water and quickly gulped down, or mixed with cooked cereal and eaten with milk and cream. Many, however, preferred to take it stirred in soup, broth or gruel, while children liked it mixed with jelly, jam, marmalade, honey, or syrup and spread on bread or toast. Bran in the form of graham bread, biscuits, pudding, soup, etc., if taken daily and in large amount, was without doubt beneficial, especially from a nutritional standpoint; but, owing to its fineness in the grinding, it did not produce such bulky stools, and so lost much of its value in habitual constipation. The dose of raw bran for the average patient was one or two heaping tablespoonfuls daily, but more than this quantity was required in some instances. Sometimes it might be necessary to continue the usual cascara or other medicinal laxative for a few days, but as soon as the habitual stool was established it should be

stopped. Bran taken at bed-time would induce an inclination to defecate shortly after rising in the morning. Among the several hundred patients to whom he had taught the bran habit there had been many who suffered from such conditions as chronic diarrhea, diarrhea alternating with constipation, mucous colitis, enema constipation, and constipation due to castor oil, saline waters, and other agents whose secondary effect was astringent.

Dr. Anthony Bassler said he was in entire accord with Dr. Gallant as to the practical utility of bran. There could be no doubt of its great value in habitual constipation, both on account of its mechanical and its pharmacological action. There were, however, a certain proportion of cases in which, although there was no anatomical condition causing obstruction, bran failed altogether. In instances of this kind we might give the patient large amounts of bran and agar daily, besides prescribing prunes, water, exercise, etc., and while the bowels might perhaps act well for a few days, they would then shut down, and it would be found necessary to supplement this hygienic treatment with cascara or other similar agent. Still, in the great majority of cases bran acted in an entirely satisfactory manner, and it was much to be regretted that it was prescribed to so small an extent by the medical profession. The principal reason for this, it seemed to him, was because bran was so cheap. It was particularly useful for children, in whom its good effect was even more noticeable than in adults.

The president, Dr. Wilcox, referred to a case bearing on the alleged special value of uncooked food. Some time since, he said, he was called as an expert on behalf of the Government in the trial of a suit involving the merits of a certain advertised food which was claimed to be curative of all sorts of diseases. The claim for the wonderful activity of this preparation was based on the asserted fact that the grain composing it was still alive; so that a person using it received all the benefit to be derived from living matter. The jury, however, decided that its alleged virtues were a pure fabrication, and the proprietor was fined by the court. The paper, he said, was one of great practical value, and he agreed with Dr. Bassler that bran was not much used from the very fact that it was so accessible and cheap.

Dr. Gallant said it was mainly the bulk of the stools resulting from bran which did the work in chronic constipation. Patients often got used to laxative drugs, so that these lost their effect, and he had found bran successful in cases where every other means had failed. He was convinced that the autointoxication which was so common was due to the accumulation of feces in the bowel, as this permitted the constant resorption of toxic matters. What was needed to prevent this was something to excite active peristalis and keep the fecal column moving, and bran was a most serviceable agent for the purpose.

The Tissue Density Factor in Physiology and Pathology.—Dr. Homer Wakefield, in this paper, said that his researches on this subject had been begun in 1893, when he published an article on the pathology of catabolism in relation to the etiology of cancer and allied states. In the past eleven years he had published a total of twenty-three monographs, most of which had presented some aspect of the subject, and he now had three volumes well advanced which would eventually elaborate it in detail. Since the appearance of his first article on cancer he had made repeated and strenuous efforts, though with only partial success, to obtain from histologists a recognition of the low organization and density tissue cell as a product of restricted metabolic factors, and not necessarily as a rudimentary form of life, a young cell, or a component of embryonic tissue, as Cohnheim had taught. Although Cohnheim had observed more facts bearing upon the question at issue than anyone else up to his time, he could see only this explanation, and it appeared paradoxical that he did not arrive at a different conclusion after experimentally producing at will in rabbits's ears, by ligating the supplying arteries, a complete loss of tissue organization, attended with confluence, hemorrhagic extravasation, increased fluidity in stagnant blood, and profound alteration in the blood where the stasis occurred. The logical deduction, from which there was no escape, that metabolic equilibrium is a balanced action between an incessant oxidative synthesis on the one hand and a destructive action of functional exercise on the other, implied a possible disequilibrium of metabolism when the opposing processes were not equal. Furthermore, certain factors, necessary to both, might retard or inhibit both, without destroying the metabolic equilibrium in that regard, yet upset it secondarily. Oxidation was such a factor, one which was both anabolic and catabolic. In ultra-degenerative processes we had the increased cell division balanced by a decreased one, with protoplasmic synthesis almost nil on the anabolic side and oxidative combustion and autolytic catalysis as nearly so on the other side. Therefore in cancerous stages of degeneration we found that any existing hyperplasia was accounted for quite exclusively by cataloblic stasis; which also accounted for the fact that the growing edge, so-called, of malignant growths consisted of an admixture of normal with degenerate cells which were above the meridian, but became progressively decadent as they approached nearer to the central zone of putrefaction. As to the biological status of tissues of low density and organization, further observation seemed to substantiate his old postulate that protoplasmic and cellular integration, organization and integrity, including density and the degree of cell complexity and differentiation, are at all times in exact ratio to the status of supply of the factors of anabolism, plus or minus the existing status of catabolism. The low density and organization status was typical, not only of the most rudimentary forms of animal life, but also of the early life-span of each individual in the higher animal life forms. Thus, cells and tissues exhibiting such a status, wherever found, had been denominated embryonic or young cells and embryonic tissues, or those reverted to embryonic or rudimentary type. The jelly of Wharton of the umbilical cord was recognized by common consent as the most characteristic of the embryonic tissues. It had long been known that, within normal limits, the more rudimentary animals were in the zoological scale, the younger the organism, and the less dense the living substance, the more rapid the growth; assimilation, synthesis, and mitosis being in equilibrium. All young animal flesh was noted for its high proportion of nucleonic elements and derivatives, and all soft, rapid-growing tumors were characterized by loss of cytoplasm, leaving a disproportionately large content of nucleonic elements. The former was the consequence of progressive, the latter of retrogressive, processes. It had also been pointed out that cell growth occurs in inverse ratio to the differentiation and complexity of the cell, or, conversely, that it grows and multiplies freely when young, while growth is retarded correspondingly to the progress of age. Next to age the relation of use and disuse of the animal tissues was one of the most important factors of tissue density and differentiation. Physiological exercise developed density and integration, while disuse brought softening and disintegration (atrophy). Any comprehensive concept of living substance must be from the viewpoint of a constantly dependent product of an incessant process of integration and disintegration, of organization and disorganization, and of differentiation and confluence; the tissue integrity at any unit of time being dependent upon the existing ratio of the two opposing forces. From this vantage ground we could view its status as an expression of the mean of the balanced action of the composing and decomposing factors. All biologists concurred in the opinion that the living organism is dependent upon the favorable or unfavorable status of environment and its successful or unsuccessful adaptation thereto. The speaker held that, in large measure, the material expression of adaptation to environment, of acquirement of immunity and the attainment and hereditary transmission of acquired characters, was one of the variations of integration and disintegration. The fall in general body oxidation, as evidenced by the temperature depression directly following birth, incident to the adaptation of the body to the new environmental temperature, was attended with metabolic retardation and decrease of assimilation and synthesis in proportion as the superficial capillary blood was determined to the great venous trunks. Thus we had the familiar cyanosis, relative polycythemia, icterus, edemas, hemorrhagicas, tetanus infections, sclerema and fatty degeneration of the newly born as a hyperesthetic reaction. The observed exaggerated reaction to cold of the peripheral tissues of infants of premature birth simply illustrated the relationship of tissue density to reaction phenomena. He dwelt for some time on the importance of the density factor of tissue structure throughout the body, and went on to say that the problem of susceptibility to infection was closely related to the density of tissue in all respects, as to invasion, favorable soil, vital resistance, reaction weakness, impaired oxidation, autolytic powers, and all the other factors going to make up the prophylactic capacity of high tissue integrity. The vulnerability of rarefied tissue to inflammatory phenomena had been shown, and especially in the higher and more violent forms of inflammation, such as diphtheria and erysipelas, were the affected and vulnerable tissues observed to be rarefied. Our attention was now directed to the interesting researches of Wassermann, who was apparently putting to practical application two previous postulates of his (Dr. Wakefield's), namely, the predisposition of rarefied tissues to

deposits of solid particles and the relation of catalytic properties to oxidation. All the fluorescent dyes undoubtedly acted as activators or accelerators of oxidation, and should be expected to be specific in those cases only where catalysis was the remiss factor. The selective determination to and action upon the diseased tissues by these dyes must depend upon the difference of surface tension and osmotic pressure. Another example of the exhibition of tissue impregnation by virtue of its loss of surface tension and osmotic pressure, incident to rarefaction, was fatty infiltration. The so-called coarseness of the integument of ultra fat individuals was due to cutaneous expansion. Having stated that contraction and expansion (extension) were expressions of the most fundamental property of irritability of living substance, he spoke of the basis of vasomotor compression by condensation, the density factor of tissue reaction, and the biological series; the latter being the name he had given to the reaction curve common to all forms of animal life and to sensitive plants. He had, he said, made a double application of the scale of reaction phenomena: first, as representative of the series of reactions incident to the tissue status of the several stage-phases exhibited, and, second, of the contraction curve of any contractile tissue which progressed to a point of maximum contraction and thence declined to a state of exhaustion-relaxation, when continued to that degree. As to the physical basis of pain, rarity of tissue and its corresponding hyperesthesia predisposed it to painful phenomena, and this fact called for the removal of pain from the domain of metaphysics and psychology to that of living substance reactions. Pain, it was observed, was caused by that which produced contraction, and its acuity depended upon the intensity of contraction and amount of tissue involved in a single contraction. To any unit of stimulation the pain involved, as the reaction expression, was inversely as the dimensions of the muscle, and thus the small muscles of the face gave rise to the most acute pain. In general, as a therapeutic measure, hyperesthetic rarities of tissues should be recondensed, and not merely relaxed. Even during painful contraction, a condensing agent, such as ergot, would produce relaxation by condensation. Pain was at its height when the phase of contraction was also at its height. The phase could be changed in either direction, either by restoring normal conditions of rest or by continuing on to exhaustion-relaxation. The latter method was the one now in vogue: we poisoned the patient so that the painful contraction might be relaxed. Painful states which were palliated by narcotics not infrequently recurred, as the recession of excursion in the biological series took place. Often the pain was manifest only on the recession, as shown in thawing after freezing of parts of the body. In speaking of the physical basis of hyperesthesia he said that in the orderly consecutive series of reaction events which he had termed the biological series, beginning at the normal point, which he called zero, the living tissues being at rest, we found: If a part be mildly stimulated by any one of the five forms of physical energy—chemical, thermal, photic, electrical, or mechanical—and after a short interval again stimulated, the second stimulation (of no greater degree than the first, which excited no reaction whatever) will excite a response that is both precocious and exaggerated-violent. In the course of a stimulation beginning at zero and gradually rising in intensity it was observed that not until a certain degree was attained was a contraction reaction elicited, and this point was termed by biologists the threshold of stimulation. When the single stimulation antecedent to that of the exaggerated response was intervaled to the succeeding one, we found that the threshold of stimulation had been attained, *i.e.* the succeeding one was promptly responded to. If a small animal were injected with a foreign serum, so small in quantity and so little toxic as to elicit no reaction, and, after a period of absorption and insensible reaction, were reinjected with the same amount of the same serum, the second reaction might be so violent as to prove fatal. In the terms of this type of research, the initial injection sensitized the animal, and the second produced anaphylaxis. If, instead of allowing an interval, consecutive injections were substituted, the violent reaction would be absent, and an ultimate state of lost reactibility arrived at. This was termed immunity or prophylaxis. In general physiology the status attained by the anteecedent stimulus was termed hyperesthesia, while in serology the production of complete adaptation to a heterologous agent would be regarded as an immunity from later reaction. Hyperesthesia, however, was a relative condition, and was governed in its intensity by the reaction vitality and reaction velocity of the reacting tissues: which, in turn, were exhibited in inverse ratio to the density of the tissue. As to the time equation of tissue reaction in relation to density, the reaction time of the mental phenomena of physiological psychology and that of tissue reaction, as related to mental function, should be sharply distinguished. Paradoxically, it was an observed fact that the speed of conception commonthly decreased in inverse ratio to the increase in velocity of tissue reaction to sensorial impressions; which thus further widened the gap between precocious reaction and delayed deliberation upon it. In other words, with exaltation of the sensibilities, the individual became more obtuse in the higher faculties of discernment, discrimination, and discretion. A fundamental law, which had stood every test for many years, might be expressed thus: The acuity, velocity, and energy expenditure of vital reaction of living tissues are in inverse ratio to the density of the same. By the aid of this law the kaleidoscope of normal and morbid mental and nervous phenomena was brought within the grasp of comprehension, without the aid of supernatural agencies. The reaction times of greatest scientific importance were those of the general or somatic organism. Tissue density varied not only with age, but also with sex; woman representing a typical mental character commensurate with her lower tissue density. The hyperesthetic individual exhibited hypersensitiveness, hyperexcitability and hyperirritability primarily, and hyperimpressionability and hypersuggestionability secondarily—all due to precocious, over-swift, and exaggerated tissue reaction. The precocity of reaction to sensorial impressions was such as to disturb the time relation of the balanced action of intellection, involving a predominance of reflex, recoil, or impulsive, as contrasted with deliberative, reaction expression. The more an individual acted on impulse, the less were his acts balanced by his previous experience and knowledge. Persons acting on impulse, when uninfluenced by others, were whimsical, capricious, fanciful, and erratic. They were the constant prey of human vultures and parasites, and were prone to fanaticism and absorbing infatuations, especially the mysterious and religious. All hyperesthetics were relatively weak, though they differed in nutrition in exhibited strength. All striped muscles were extended in equilibrium length, and smooth muscles and supporting ligaments sagged according to their loss of density, which implied expansion and extension. That the mental function had long been regarded as a balanced action was attested by the common reference to well-balanced and unbalanced minds, but Dr. Wakefield said he did not know of any definite efforts to study the nature of the unbalancing. His own insight into this subject had been born of observation of the inequalities exhibited by hyperesthetic individuals. The correlation existing between the direct reaction to sensorial impressions and the deliberative-conscious reaction to the same, as regards cooperation, relative velocity, reactions, etc., were found to be of great importance. Hyperesthesia was expressed by exaggerations of the most commonplace acts of every-day life, and physiological activities were exaggerated into pathological ones. Thus, for instance, the sexual instinct might be exaggerated into erethisms, satyriases and nymphomanias. So long as the tissues continued in a rarefied, relaxed state, mentality was distorted, and the hyperesthetic was unethical for the reason that he did not deliberate upon the rights, feelings, and needs of others, as well as on account of his instinct of self-protection. In concluding, he said that when the pathogenesis and pathology of any derangement was thoroughly understood, the therapeutics was much simplified and the prophylaxis clearly indicated. Knowing that the greatest tissue density comes from the highest degree of the process of integration, that the latter in turn depends upon oxidation synthesis, and this upon oxygenation, normal alkalinity, and catalytic activation of the chemical processes, and all their subdivisions, the physician would find his hands very full in spanning the ever-widening field of prevention and treatment. For example, oxygenation would include nasal, laryngeal, and pulmonary respiration, and cardiac, vascular, and hemic factors of circulation and oxygen-carrying capacity of the blood and hyperesthetic reaction-exsanguination of the capillaries would present both local and general significance as vascular factors. The many sources of acid factors and subalkalescence would have to be taken into consideration. The part played by the catalytic elements of the thyroid and thymus glands, as well as general glandular catalytic activities, required attention, and where the secretions of the glands were deficient, these should be artificially supplied as a correction. The direct action of the secretion of the suprarenal glands in the attainment and regulation of tissue density also demanded a hearing. Not only did the factors of the body requiring possible attention

confront the physician, but, in addition, habits of life not infrequently had to be materially changed. Ill-ventilated super-heated indoor atmospheres had to be replaced by fresh, cold outside air, hot baths by cold ones, rest cures by work cures, and coddling by discipline; while sedentary habits had to be exchanged for physical training, muscle development, and general tissue hardening. Frequently physical and mental capacity had to be partially restored to make possible the cooperative participation of the patient. This was to be attained by artificial tissue condensation, and could probably be most promptly accomplished by hypodermatic injections of ergot according to Livingston's method. The so-called cumulative effects of progressively increasing doses of such drugs as nux vomica and strychnine, thus obviating their contraction-producing action, Dr. Wakefield regarded as tissue-condensing in their ultimate results. One of the exaggerated reactions, fear, which as an emotion was harmful, had of late been exploited as a universal cause of the woes of the neuroses and psychoses, not only by the several faith-healing cults, but by some medical writers who should have been better informed. When all was traced to the fear root, a purely mental form of treatment appeared to be the only logical one.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 9, 1912.

DR. WILLIAM SHANNON IN THE CHAIR.

Osteogenesis Imperfecta: Report of a Case with the Study of Its Metabolism.—Drs. HERMAN SCHWARZ and MURRAY H. BASS presented this paper. They stated that the condition known as osteogenesis imperfecta did not enter into the symptom complex known as fetal rickets. Attention had been called to cases characterized by fragility of the bones by Lobstein in 1833, and he gave the condition the name of osteopsathryosis, and showed that there was a group which was termed idiopathic for which there was no definite etiological factor. A further study of osteopsathyrosis and osteogenesis imperfecta, both clinical and pathological, showed that these were identical conditions. The greatest number of cases occurred during intrauterine life and were still-born. A few, however, survived and presented definite clinical characteristics. One group of these cases appeared to be normal at birth, but later on in childhood suddenly developed a tendency to multiple fractures from very little violence. Many authors were of the opinion that these cases were congenital, but that the process had lain dormant. Heredity seemed to be the only important etiological factor. In one instance it had been noticed that the disease was present in one of twins, the other child being normal, and this would tend to show that the actual condition of the mother was not at fault and that the disease was a fetal one. Macroscopically the bones showed fractures, the breaks being very numerous in some instances. The bones might be soft and pliable or very brittle and they might be either normal in length or short and plump, scarcely narrower in the middle than at the ends. The cortex of the bone was extremely thin. The bones of the skull were characteristic in that they were almost entirely devoid of calcification. The base of the skull was usually ossified, but was thin and friable. The ribs also were ossified, but showed irregularly distributed nodules representing previous fractures. Microscopically the region between the epiphysis and diaphysis of the long bones showed normal relations in respect to the proliferation of the cartilage, the form, structure, and arrangement of the cells. Endochondral ossification *per se* proceeded normally, but was markedly reduced in amount. In the diaphysis one met with numerous thin cartilage remnants, but with very few bone trabeculæ. Periosteal ossification was entirely absent in certain places; in others it was slight. The periosteum was thin and the number of osteoblasts everywhere diminished; in the long bones the marrow was markedly increased. The children who survived with this condition were small, underweight, had long silky hair, open fontanelles and sutures, small faces, soft delicate skin, protuberant abdomen without any evidence of umbilical hernia, and diastasis recti. The extremities showed all sorts of deformities due to fractures, bending, marked shortening, and curvature being the rule. The fractures seemed to cause very little pain and union took place rapidly. The *x*-ray appearance of the bones showed large medullary cavities with very thin atrophic cortex; epiphyseal lines showing up very sharply. The prognosis of the disease was bad. It was better in cases occurring late in childhood, and some cases seemed to undergo spontaneous cure. The case reported was that of an infant seven months of age, whose family history was negative as to syphilis, tuberculosis, or any bone disease similar to this one. When the child was four days old the physician found a fracture of the thigh, but the mother knew of no other fractures. Except for underdevelopment and deformities, the child seemed normal. The head was abnormally large in comparison with the trunk and the extremities were small, shortened, curved, and angulated. The sagittal suture was wide open. There was distinct exophthalmos. The nostrils were fine and delicate, the mouth small, lips thin, tongue slightly protruding, and the hair long and silky. The clavicles showed angular deformity. Lymph nodes the size of a pea were just palpable in the axilla and groin. The urine was clear, amber, acid, and showed no albumin or sugar. The blood showed hemoglobin, 60 per cent.; red blood cells, 4,512; white blood cells, 11,600; differential polynuclear leucocytes, 15½ per cent.; large mononuclears, 17 per cent.; small leucocytes, 64 per cent.; eosinophiles, ½ per cent. The Noguchi modification of the Wassermann reaction was negative. The child was placed in the Hoobler metabolism bed for six days and was fed on mixed human milk. The weight of the child at the beginning of the experiment was 4300 grams. During the six days the child took 3390 c.c. of milk, appeared to be in normal health, and the tables showed that nitrogen metabolism was normal. The excretion of creatinin nitrogen by the kidneys was low as compared to the findings of Amberg and Morril. The fat absorption and retention were perfectly normal. The calcium metabolism was of particular interest in the light of the disturbance in the ossification of the bones. The child, according to the tables, was retaining calcium to the extent of 45.7 per cent. of the intake. The truest view as to the calcium retention was obtained when the retention was based, not on the per cent. of intake, but on the absolute amount retained. A comparison of this baby with others showed that a retention of 109 mgs. did not appear to be very low, the average retention being from 210 to 120 mgs. The positive calcium balance in this case might be construed in different ways. The disease might be considered at an end as there had been no fractures since birth, and the calcium metabolism might be looked at as that of a normal child. But the cranial bones were still soft. The disease might be in the stage of repair, and this seemed likely since there had been no fractures since birth. But, again, if the body was trying to replace lost calcium, there should have been a decidedly greater retention of calcium than was present in the normal child. This was not the case. When one considered how complicated the whole calcium metabolism was, such a case as the one under discussion led one to speculate as to whether there was a distinct relationship between calcium retention and skeletal ossification. The retention of magnesium was 51 per cent., which showed very little variation from the other cases in which it had been determined by Blauberg. The phosphorus metabolism was practically normal, while both sodium and potassium were positive, but it was impossible to discuss their significance in view of the small number of existing analyses in normal infants. For the same reason the sulphur balance could not be adequately discussed.

Scleroderma in an Infant.—Dr. ROGER H. DENNETT reported this case. The history of the child showed that she was born on October 8, 1911, and weighed six pounds at birth. She was the first child of healthy parents, and, so far as could be ascertained, was perfectly normal at birth. When three days old she became very ill and her life was despaired of. In the course of a week the physician said to the mother that it would be just as well if she did not live as she was not a normal child; all her joints were stiff. She recovered, however, and gained in weight. At the end of two months she still had rigidity all over the body and thickening of the skin and subcutaneous tissues. A physician who saw her at that time made a diagnosis of arthritis due to syphilis. The *x*-ray plates taken showed lack of ossification in the carpal and tarsal bones. The child was put on mercurial inunctions for about a month and did badly. This was of interest in view of the statement made by some authorities that scleroderma was aggravated by mercury. Dr. Dennett had first seen the child when she was three months of age. She then weighed seven pounds and twelve ounces and seemed normal mentally. The skin over her entire body, with a few exceptions, was yellow, waxy in appearance, perfectly smooth, soft, moist, thickened, and indurated, not pitting on pressure. The fontanelle was normal in size and the head well-shaped with no thickening about the scalp. The arms were normal, the hands having a small amount of thickening on the dorsal aspect, and the fingers were held

flexed like congenital club hand. The legs were held in the flexed position and could not be extended, even with a great deal of force. The medicinal treatment was stopped and more frequent nursings given. The vomiting was controlled to a certain extent by paregoric. Very energetic massage was given to prevent ankylosis. The subsequent history of the case was not of great moment. Three weeks ago the administration of thyroid extract was begun; this was only because no treatment had as yet been satisfactory and because the induration seemed to resemble that of thyroid deficiency to some extent. This was not a common condition in infancy, the youngest case on record as far as the author could ascertain being that of a child thirteen months of age. The disease was apt to run a shorter course in children, and therefore the prognosis was better. This condition should not be confused with scleremа, the latter running a subnormal temperature and the indurated areas being of a bluish color, cold and clammy to the touch.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

GRUNDRISS DER BIOCHEMIE. By Prof. CARL OPPENHEIMER. 399 pages; illustrated; cloth; price 9 M. Georg Thieme, Publisher, Leipzig.

REPORT OF THE COMMISSIONER OF EDUCATION FOR THE YEAR ENDED JUNE 30, 1911. Vol. I. 675 pages; cloth. Published by The United States Bureau of Education Washington.

GEWURZE BEI NEPHRITIS. By Priv.-Doz. Dr. A. KAKOWSKI. 22 pages; paper. Georg Thieme, Publisher, Leipzig.

DYSENTERY IN FIJI DURING THE YEAR 1910. By P. H. BAHR, M.A., M.B. 77 pages; illustrated; paper; price six shillings net. Witherby & Co., Publishers, London.

KRANKHEIT UND SOZIALE LAGE. By Prof. Dr. MOSSE and Dr. G. TUGENDREICH. No. 1. 232 pages; paper; price 6 M. J. F. Lehmanns, Publisher, Monchen.

CAISSON SICKNESS AND THE PHYSIOLOGY OF WORK IN COMPRESSED AIR. By LEONARD HILL, M.B., F.R.S. 255 pages; illustrated; cloth; price $3.00 net. Longmans, Green & Company, Publishers, New York.

CLINICAL DISORDERS OF THE HEART BEAT. By THOMAS LEWIS, M.D., D.Sc., M.R.C.P. 104 pages; cloth. Shaw & Sons, Publishers, London.

THE LIFE AND WORK OF WILLIAM PRYOR LETCHWORTH. By J. N. LARNED. 472 pages; illustrated; cloth; price $2.00 net. Houghton Miflin Company, Publishers, Boston.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. By Dr. L. KATZ, Dr. H. PREYSING and Dr. F. BLUMENFELD. Vol. I. Second Half. Nos. 4 and 5. 111 pages; illustrated; paper; price 8.50 M. Curt Kabitzsch, Publisher, Würzburg.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

INDIANA STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION.

July, 1911.

(*Concluded from page 227.*)

OBSTETRICS.

1. Give the physiology of impregnation.
2. Describe the development of the fertilized ovum.
3. What is meconium, and what are its diagnostic relations?
4. Describe the human uterus and give its anatomical relations.
5. Describe the vitellus, allantois, and the amnion.
6. How soon after confinement should a woman menstruate?
7. State some of the causes of sterility.
8. What conditions have a bearing on the time of life in the female when menstruation first occurs?
9. Are maternal impressions transmitted to the child in utero to such an extent as to produce marks, defects, and abnormalities?
10. Describe Credé's method of prophylaxis for ophthalmia neonatorum.

GYNECOLOGY.

1. Differentiate cystocele from (*a*) an anterior vaginal hernia, (*b*) a tumor situated in the vaginal wall.
2. Define prolapsus of the uterus and give differential diagnosis and treatment.
3. Define: (*a*) menorrhagia, (*b*) amenorrhea, (*c*) dysmenorrhea.
4. Give differential diagnosis and treatment of gonorrheal vaginitis.
5. Give technique for complete abdominal hysterectomy.
6. How would you distinguish shock from secondary hemorrhage?

SURGERY.

1. Define odontoma. Give varieties and origin of each variety.
2. Give symptoms and signs of cervical rib and how does cervical rib give symptoms and signs?
3. What is meant by coxa vara? What causes it?
4. Name the chief forms of spina bifida.
5. What is meant by Charcot's disease of a joint? What are its chief diagnostic features other than the general signs of tabes?
6. In middle meningeal hemorrhage, what extracranial treatment do you know of and what is its value? What caution is to be exercised, and why?
7. Describe operation for epithelioma of lower lip.
8. Name a few of the most important diagnostic points in ulcer of the duodenum and explain. Give physiological reasons.
9. What are the contraindications to surgery in gallstone in the common duct, and why?
10. What is a ranula?

PEDIATRICS.

1. Give symptoms and modern treatment for poliomyelitis.
2. Give cause and proper treatment of acute dysentery.

OPHTHALMOLOGY AND OTOLOGY.

1. Give causes, diagnosis, and treatment of chronic glaucoma.
2. Give causes, symptoms, and treatment of phlyctenular keratitis.
3. Give the origin of the acoustic nerve and its distribution in the labyrinth.

MEDICAL JURISPRUDENCE.

1. State fully what are the legal obligations of a physician or surgeon to his patient and what is his liability for malpractice.
2. State your ideas as to the conduct of a physician on a witness stand, including the manner of giving his evidence and the nature of it; also state conditions under which you would voluntarily testify as an expert witness.

RHINOLOGY AND LARYNGOLOGY.

1. Name seven diagnostic points of chronic hyperplastic ethmoiditis.
2. Name four contraindications to surgical treatment of the tonsils.

NEUROLOGY.

1. Give the six most important symptoms of tabes dorsalis.
2. Give the most significant symptoms of paralysis agitans.
3. How is migraine distinguished from other forms of headache?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

INDIANA STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION.

July, 1911.

(*Concluded from page* 230.)

PRACTICE.

5. *Average duration of the febrile stage*, in *typhoid fever*, is about three or four weeks; of *scarlet fever*, is about five or six days; of *measles*, is about five days; of *rheumatic fever*, is about one or two weeks; of *pneumonia*, is about nine or ten days.

6. Lightning pains, loss of knee-jerk, Argyll-Robertson pupil, optic atrophy and ptosis, gastric and other crises, ataxia, incoordination, and Romberg's sign.

7. *Hysteria.* The following summary of diagnosis is given by Anders and Boston: "A peculiar mental and physical condition, characterized by suggestibility of symptoms which may be of any character. The patient is usually a young adult who is emotional, irritable, and one who constantly complains and thinks of herself, and perverts everything which may occur as having something to do with her own condition. There may be headache, backache, pains in various portions of the limbs, numbness or pin-and-needle-like sensations, hemianesthesia or anesthesia anywhere, points of tenderness in the back, ovarian and mammary region, increases of reflexes, paralyses of various sorts, contractures, tremors, disturbance of vision, smell, and taste, and convulsive attacks which may assume almost any character. The most important point of all is the suggestibility of all the symptoms, their variance from day to day, and the fact that any or all may be removed by persuasion."

8. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs*: Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

The treatment consists of: Plenty of fresh air, sunshine, and sunlight, pure water, good food, exercise in moderation, and proper hygiene in general.

9. Scarlet fever, measles, and typhus fever.

10. Tonsillitis.

OBSTETRICS.

1. Impregnation is the result of the meeting of a live and healthy spermatozoon, with a live and healthy ovum, in a suitable medium (generally the Fallopian tube). During coitus the seminal fluid is ejected into the upper part of the vagina and against the cervix of the uterus; the spermatazoa enter the uterine cavity (either by the suction of the uterus or by their own vibratile motion) and so pass on to the Fallopian tube.

2. *Development of the fertilized ovum.* "(1) When the ovum is mature, two small cells are detached from the main body of cells; these are called polar globules. It was formerly supposed that these were associated with the disappearance of the germinal vesicle, but recent experiments have demonstrated that the germinal vesicle plays an active part in their formation. This can take place independently of fecundation. (2) The portion of the ovum remaining after the throwing off of the polar globules is called the 'female pronucleus.' (3) Fecundation is effected by the penetration of the head of one spermatozoon. This is called the 'male pronucleus.' (4) The male and female pronucleus coalesce. The ovum is now called the oösperm, or blastosphere. (5) The *segmentation* of the nucleus and vitellus, *i.e.* they both split into two masses, these into four, and so on until a large number of segments are formed. This is known as the morula, moriform body, or mulberry mass. (6) A clear fluid is secreted within the ovum, which presses these segments to the surface of the ovum, where they form a double layer of cells, differing somewhat in size. The outer and larger is termed the *epiblast* or *ectoderm*, and the inner and smaller the *hypoblast* or *endoderm*. Together they are known as the blastodermic vesicle. (7) There then appears upon the outside of the vitellus a small oval elevation, surrounded by a depression, which is called the *area germinativa*. (8) There appears in the area germinativa a small, dark line called the *primitive trace*. About this line will be grouped the various parts of the embryo, the rest of the ovum serving only as a covering and for nutriment. (9) A covering for this trace or embryo is now formed. Thus far the vitelline membrane has been sufficient. The embryonic line sinks into the center of the ovum, while the edges of the external blastodermic layer about the area close around it, inclosing it in a sac called the *amnion*. Between the amnion and the embryo, fluid at a later period is deposited; this constitutes the liquor amnii. The vitelline membrane then disappears."—(Landis's *Obstetrics.*)

3. *Meconium* is the name given to the stools of the newborn (or unborn) infant; they are of a green-black color, and are composed of intestinal mucus, bile, epithelial cells, cholesterin, vernix caseosa and phosphates. The continuous passage of meconium from the vagina of the parturient woman during labor indicates a breech presentation. Its discharge in undoubted head or transverse presentations is indicative of impending or actual death of the fetus.

4. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. It is pear-shaped, and lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, rectouterine, ovarian, and uterosacral. The arteries are the uterine and ovarian; the nerves are from the uterovaginal plexus, the hypogastric plexus, and the vesical plexus.

5. The *vitellus* is the yolk or germinal part of the ovum together with the substance intended for the nutrition of the embryo. The *allantois* is a fetal membrane developing from the lower part of the alimentary canal very early in fetal life; it enters into the formation of the urinary bladder and also of the umbilical cord and placenta.

The *amnion* is the innermost of the fetal membranes; it surrounds the fetus and is continuous with it at the umbilicus; it secretes the liquor amnii, and forms the sheath of the umbilical cord.

6. A woman usually menstruates about two or three months after her confinement if she *is not* nursing her child, and about seven months after the confinement if she *is* nursing her child.

7. Causes of sterility: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix. The above all refer to the female, but the trouble may be with the male.

8. Climate, race, occupation, and mode of life.

9. It is not *proved* that maternal impressions will produce marks, defects and abnormalities in the fetus. Some *coincidences* have been observed.

10. Credé's method of prophylaxis consists in cleansing the eyes with warm sterile water, and then instilling into each eye a few drops of a two per cent solution of nitrate of silver. The eyes should be treated in this way two or three times a day so long as there is any danger of contracting ophthalmia.

GYNECOLOGY.

1. In *cystocele*, part of the bladder projects into the anterior vaginal wall, and a sound passed through the urethra into the bladder can be freely felt through the anterior vaginal wall; further, it may be impossible to empty the bladder without pushing up the anterior vaginal wall.

In *vaginal hernia*, the bladder is not involved, the hernia will contain intestine or omentum or both, there may be an impulse on coughing.

In a *vaginal tumor* there will be none of the positive symptoms of the two other conditions.

2. *Prolapse of the uterus* is the condition in which the uterus lies low down in the vagina, but does not protrude through the vagina.

Differential diagnosis: In the case of *polypus* the body and fundus of the uterus are in their normal position in the abdomen, a sound can be passed into the uterus, the uterine and cervical canals are not obliterated, the polypus does not bleed easily, and is not particularly sensible to

pain. The *inverted uterus:* shows absence of body and fundus from normal position, will not permit passage of a sound into uterine cavity, the uterine and cervical canals are absent, the inverted uterus tends to bleed easily, and is very sensible to pain. In *prolapse* the largest part of the tumor is above; the opening of the Fallopian tubes cannot be seen; a sound can be passed into the uterine cavity.

Treatment: The uterus should be replaced; the vagina packed with a tampon; a pessary or colpeurynter may be employed; where the round ligaments are relaxed Alexander's operation may be performed.

3. *Menorrhagia* is an excessive hemorrhage from the uterus at the ordinary menstrual periods.

Amenorrhea is absence of menstruation.

Dysmenorrhea is unduly painful menstruation.

4. GONORRHEAL VAGINITIS. *Symptoms:* Pain and burning in the vulva; pain and burning on micturition; dyspareunia: yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Differential diagnosis* is made by the finding of the gonococci. *Treatment:* Rest in bed, salines, mild unirritating diet, bathing of external genitals, copious vaginal douches of bichloride of mercury 1:2000 three or four times a day; later, the vagina may be swabbed daily with a solution of nitrate of silver 1 to 5 per cent., or with a solution of potassium permanganate 1 per cent. *Complications:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands.

5. *Abdominal hysterectomy.* "The patient must be carefully prepared as for any other abdominal operation, but in addition the pubes and vulva must be shaved and thoroughly purified; the vagina should be douched for some days previously, and an antiseptic dressing worn, and if need be the uterine canal should be curetted and disinfected with some powerful antiseptic.

"After anesthesia has been induced the Trendelenburg position is adopted, and an incision of suitable length made in the median line. The parts are then carefully explored, and if no adhesions exist an abdominal cloth is packed in over the intestines in order to protect and keep them from exposure and injury. If adhesions to omentum or gut are present they must be carefully divided; it is, of course, most desirable that a complete peritoneal covering should be secured for any adherent organs; omental grafts may be sometimes useful in this direction. The broad ligaments are then examined, and a decision made as to whether or not the ovaries and tubes are to be saved.

"A pedicle needle carrying a sufficient length of well-boiled silk is carried through the round ligament so as to secure the ovarian artery and veins, and tied as far away from the uterus as possible. A broad ligament clamp may then be placed in position close to the uterus, so as to prevent venous regurgitation, and the broad ligament is divided half-way down. It is often possible and desirable to pick up the divided end of the ovarian artery on the face of this section and secure it separately, while the little artery which accompanies the round ligament should also be carefully secured. The ovarian artery on the other side is next dealt with in a similar fashion. A transverse cut is now made across the front of the uterus, involving merely the serous membrane and connecting the two ends of the incisions in the broad ligaments; the peritoneum below this transverse cut is detached, together with the bladder, from the cervix, and the intraligamentary space is thereby opened up on either side. In this will be found the uterine vessels, and it may be possible to see and isolate the uterine artery before securing it by ligature. Care must be taken in this part of the operation to keep close to the uterus, as the ureter comes forward from behind under the uterine artery to reach the bladder, lying about the level of the os internum. The uterine vessels are in this way carefully secured and divided.

"The uterus is now merely held by the connection between the vagina and cervix and the peritoneal reflection in Douglas's pouch. If a supra-vaginal operation will suffice, the surgeon cuts across the neck of the uterus in such a way as to fashion two flaps, and finally the peritoneum behind is divided. A few small vessels will probably need to be secured on the face of the uterine stump. This having been effected, the uterine flaps are stitched carefully together so as to bury the open cervical canal; the uterine stump is then covered in by uniting the divided portions of peritoneum. This line of sutures is carried up on either side so as to secure the two layers of the broad ligament; the final result is that the pelvic floor is covered in by a continuous layer of peritoneum, showing a sutured incision which runs transversely from one side to the other. The usual peritoneal toilette follows, and the abdomen is generally closed entirely, no drainage being required."—(Rose and Carless' *Surgery.*)

6.

SHOCK.	SECONDARY HEMORRHAGE.
1. Generally follows a prolonged operation or one in which the abdominal viscera have been exposed to the air or more or less roughly handled; it is also likely to occur in women who are weak and exhausted physically.	1. May follow either a severe or a simple operation; the general condition of the patient does not influence its occurrence.
2. The patient is listless and apathetic and there is seldom any tendency to toss about in the bed.	2. The patient is restless and her mind apprehensive and anxious.
3. Seldom recurrent attacks of syncope.	3. Recurrent attacks of syncope frequent.
4. Pulse and general condition not satisfactory immediately after operation and the symptoms of collapse come on suddenly.	4. The patient recovers from the anesthetic in a good condition, but later on the pulse gradually becomes accelerated, the temperature falls below normal, and collapse finally intervenes.
5. General stimulating treatment tends to improve the pulse.	5. The pulse progressively grows worse despite all that is done to stimulate the heart and secure reaction.
6. The blood findings are negative.	6. There is a moderate leukocytosis (15,000 to 25,000); the number of red cells and the percentage of hemoglobin are diminished (Martin and Hare); the blood-plaques are increased in number; and the coagulation time of the blood is more rapid.

(Ashton's *Gynecolgy.*)

SURGERY.

1. An *odontoma* is a tumor composed of tooth tissue. *Varieties:* (1) Follicular odontomes, or dentigerous cysts, generally arise from the follicles of the permanent molars. (2) Fibrous odontomes, due to thickening of the tooth-sac. (3) Cementome, due to enlargement and ossification of the capsule. (4) Compound follicular odontome, from the capsule. (5) Redicular odontome, from the papilla. (6) Composite odontome, from dentine, cement, and enamel.

2. A cervical rib may not give any signs or symptoms; when such are present they are due to pressure on brachial plexus or some blood-vessel. It may cause subclavian aneurysm, neuritis, or gangrene of hand. There may be pain, weakness of the arm, trophic disturbances, or obliteration of the pulse. The *x*-rays confirm the diagnosis.

3. *Coxa* vara is a condition in which the neck of the femur is bent downwards so that the angle between the neck and shaft of femur is lessened; the hip joint is healthy. *Causes:* Rickets, impacted fracture of neck of femur, slipping of the epiphysis, and atrophy of the neck of the femur, with osteoarthritis.

4. *Varieties of spina bifida:* (1) *Myelocele,* in which the central canal of the spinal cord lies open on the skin surface of the body (incompatible with life). (2) *Syringomyelocele,* in which the central canal is dilated, so that a portion of the spinal cord is spread out over the interior of the sac. (3) *Meningomyelocele,* in which the meninges remain adherent to the skin, fluid collects within them, and the spinal cord and nerves run down the posterior part of the sac. (4) *Meningocele,* which is a protrusion of the membranes containing cerebrospinal fluid but neither nerves nor spinal cord. (5) *Spina bifida occulta,* in which there is no tumor except perhaps a lipoma or a dermoid with hair.

5. Tabetic arthropathy, or an osteoarthritis.

The *joint signs* are: "(1) Very rapid and painless onset usually occurs. (2) A great synovial distention is the first feature. (3) All the signs of osteoarthritis, viz., enlargement of the bone ends, clipping of articular margins, coarse grating, quickly follow. (4) Marked absorption of bone, with consequent shortening or deformity. (5) Massive heaping up of new bone as an outgrowth round the articular margins, in the hypertrophic varieties. (6) Disorganization or dislocation of the joint from a yielding of the ligaments and destruction of the joint surfaces. (7) Absence of all pain or tenderness is a conspicuous and characteristic feature."—(*Synopsi of Surgery.*)

6. In middle meningeal hemorrhage trephining is often of value because the hemorrhage may be located, the clot turned out, and the artery ligated. It is often difficult to know exactly where to trephine, for the main hemorrhage often occurs not at the point of application of the injury, but on the other side of the cranium.

7. In *epithelioma of the lower lip* there should be thorough and early excision; incisions should be at least half an inch from the tumor. The glands in the submaxillary and submental triangle should also be removed. Dowd's operation is recommended.

8. In *ulcer of the duodenum* the symptoms are very similar to those found in ulcer of the stomach; but in the former condition there is less tendency to vomit, the pain does not come on till some time after food has been swallowed (and has had time to pass the pylorus), and blood in the stools is more common. All of these points are due to physiological and anatomical reasons based on the relative position of the stomach and duodenum. A special sign of duodenal ulceration is the so-called "hunger pain" which occurs at the end of digestion, when the unmixed acid of the gastric juice is passing into the duodenum. This pain is relieved by taking food, for when this occurs the pylorus closes, and the gastric juice is for the time retained in the stomach to be mixed with the food, while the alkaline duodenal and pancreatic secretions are stimulated.

9. *Contraindications to surgery in gallstone in the common duct:* (1) Obstructive jaundice, because operation is then dangerous, owing to the possibility of fatal oozing of blood. (2) In non-patency of the common duct.

10. A *ranula* is a cyst under the tongue, due to dilatation of one of the sublingual ducts.

PEDIATRICS.

1. Poliomyelitis. *Symptoms:* "The onset of the affection varies; it may be acute, subacute, or chronic; it is usually sudden, with an attack of mild fever of a remittent type, of a few days' duration, on recovery from which it is noticed that the child is paralyzed. Rarely the paralysis may be preceded by convulsions. The paralysis may affect both arms and both legs, the legs alone, or only one of the four extremities; it may, very rarely, be a hemiplegia. As a rule, however, the leg suffers more frequently than the arm; in paralysis of the leg the muscles below the knee suffer more severely than those above. The bladder and rectum are not affected, or, if so, only temporarily, and anesthesia or numbness cannot be detected. The temperature of the paralyzed limb is low and the part is cyanosed in appearance. After a few days there is a slight improvement in the paralyzed parts, although the muscles show a rapid wasting, which is progressive until all muscular tissue is gone. The reflex movements are impaired or abolished. The electro-contractility by the faradic current is abolished in the paralyzed parts. With the galvanic or constant current the 'reactions of degeneration' are developed."—(Hughes' *Practice of Medicine.*)

Treatment: "During the febrile stage the patient should be placed at rest in bed and all the secretions rendered free. If the affection is suspected at this period the limbs should be wrapped in cotton-wool and ergot administered to lessen the spinal congestion. Counterirritation is unnecessary. As soon as the febrile reaction has subsided and the paralysis becomes manifest the child should be well fed and taken outdoors once daily. Gentle friction should be applied to the affected muscles at first, followed later by the hot spinal douche and mild galvanism. Internally, quinine, belladonna, ergot, and potassium iodide may be of value. Later, as improvement takes place, tincture of nux vomica, ♏i to iii, three times daily, or hypodermic injections of strychnine sulphate, gr. 1/100 to 1/16, according to the age, twice a week, and faradism to the paralyzed muscles, are to be used. Means should be taken to prevent deformities."—(Hughes' *Practice of Medicine.*)

2. Dysentery. *Cause:* The *Bacillus dysenteriæ. Treatment:* Rest in bed, a dose of salts, castor oil, with laudanum, irrigation of the colon, liquid diet, ipecac, and serum treatment.

OPHTHALMOLOGY AND OTOLOGY.

1. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness. *Treatment:* Miotics, such as eserine or pilocarpine; massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy.

2. *Phlyctenular keratitis* "is usually associated with phlyctenular conjunctivitis in children of scrofulous diathesis, but may occur in others. It is characterized by one or more small cysts found on the limbus of the conjunctiva and extending upon the cornea. The symptoms are acute pain, photophobia, lacrimation, and the characteristic bundle of vessels, with a yellow crescent at the apex, its concavity toward the apex. Blepharospasm is present and may be severe. The treatment consists of good food, fresh air, and the administration of tonics and stimulants. Locally, atropin and warm compresses should be used, and the eye douched with mercuric chlorid solution 1:8000. Later, iodoform or calomel may be dusted in the eye and massage with the yellow salve may be practised. Absorption of the vessels may be hastened by the instillation of eserin, dusting with iodoform, and the application of a binder."—(Gould and Pyle's *Pocket Cyclopedia.*)

3. The acoustic nerve has its superficial origin between the pons and restiform body, the floor of the fourth ventricle, by the lineæ transversæ. Its deep origin is from the lateral angle of the fourth ventricle and from the inner auditory nucleus. At the bottom of the internal auditory meatus it divides into the cochlear and vestibular nerves. The *cochlear* supplies the cochlea and posterior semicircular canal; the *vestibular* supplies the vestibule and superior and external semicircular canals.

MEDICAL JURISPRUDENCE.

1. A physician is not at all bound to accept a professional call; but if he accepts he is bound to continue in attendance until the patient no longer requires his services, or he is discharged. He can leave during the continuance of the condition for which he was called only after giving ample notice of his intention to discontinue his services, and allowing a reasonable time for the patient to obtain the services of another physician. The physician undertakes to use proper skill, care, and judgment in diagnosing and treating the case, and also to give full instructions as to how the patient may be best cared for. The patient undertakes to allow the physician ample opportunities to make his diagnosis, to give him all information in his power, to obey instructions, and to pay a proper fee. The physician is not allowed to divulge anything that he learned while in professional attendance, provided such knowledge was necessary to the successful conduct of the case.

Malpractice is a failure on the part of the medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

2. The following, which admirably answers this question, is from Witthaus and Becker's "Medical Jurisprudence":

(1) A physician should refuse to testify as an expert unless he is conscious that he is really qualified as an expert.

(2) After accepting the responsibility, his first duty should be to make a diligent examination and preparation for his testimony, unless it be upon a subject with which he is familiar, and which he is satisfied that he has already exhausted, by reading the best authorities that he can find, and by careful reflection upon particular questions as to which his opinion will be asked.

(3) Where he is to make an examination of facts, such as the post-mortem examination of a body, a chemical analysis, or an examination of an alleged insane person, he should insist upon having plenty of time and full opportunity for doing his work thoroughly. He should take particular pains to make his examination open and fair, and, if possible, should invite opposing experts to cooperate with him in it.

(4) He should be honest with his client before the trial in advising him and giving him opinions, and upon the trial should observe an absolutely impartial attitude, concealing nothing, perverting nothing, exaggerating nothing.

(5) On the preliminary examination as to his qualifications as a witness, he should be frank and open in answering questions. He should state fully the extent and the limits of his personal experience and of his reading upon the subject, without shrinking from responsibility, yet without self-glorification.

(6) He should be simple, plain, and clear in his statement of scientific facts and principles, avoiding the use of technical language, and trying to put his ideas in such form

that they will be grasped and comprehended by men of ordinary education and intelligence.

(7) He should avoid stating any conclusions or principles of which he is not certain, but having an assurance that he is right he should be firm and positive. He should admit the limitations of his knowledge and ability. Where a question is asked that he cannot answer, he should not hesitate to say so, but he should refuse to be led outside the subject of inquiry, and should confine his testimony to those scientific questions which are really involved in the case, or in his examination of the case.

(8) He should always bear in mind that at the close of his testimony an opportunity is usually given him to explain anything which he may be conscious of having said which requires explanation, and partial statements which need a qualification to make them a truth. This is the physician's opportunity to set himself right with the court and with the jury. If the course of the examination has been unsatisfactory to him, he can then, by a brief and plain statement of the general points which he has intended to convey by his testimony, sweep away all the confusion and uncertainty arising from the long examination and cross-examination, and can often succeed in producing for the first time the impression which he desires to produce, and can present the scientific aspects of the case briefly and correctly.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery.	Montgomery	..
Arizona*	J. W. Thomas, Phoenix	Phoenix	Oct. 7
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 12
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco	San Francisco	Aug. 6

Wyoming	A. B. Tonkin, Riverton	Riverton	..

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

The Increasing Consumption of Alcohol and Tobacco.—Although the sale of alcoholic drinks is prohibited over a large section of the United States, the consumption of the same is steadily increasing. According to the report of the Commissioner of Internal Revenue for the year ending June 30, 1912, 188,000,000 gallons of whiskey was produced, or 13,000,000 gallons more than in the previous year. The number of cigarettes smoked during the year was 11,221,624,084, exceeding the record of the previous year by nearly 2,000,000,000. The consumption of beer fell off 1,108,000 barrels.

Medical Items.

Pneumococcic Laryngitis Followed by Suppurative Arthritis, Endocarditis, Septicemia, and Death.—A. Abrahams reports the case of a man, aged forty-five years, who was admitted to the hospital with urgent dyspnea and stridor of three days' duration. The onset of the disease was said to have been sudden. The larynx was edematous and intensely red. He had slight bronchitis and a temperature of 102.6° F. The urine was very scanty and contained 0.1 per cent. of albumin. He had slight edema of the hands and legs. Cultures from the throat showed a majority of pneumococci. During the next four days the patient steadily improved, the larynx recovered, and it was thought that he might soon be well enough to leave the hospital. On the sixth day he had a rigor, with a temperature of 104.6° F. He then had daily rigors for six days, when he complained of pain in the right shoulder joint. Exploration revealed thick, ropy pus in the subacromial bursa, which pus gave a pure growth of streptococcus. Some improvement followed for a few days; afterwards there were daily rigors, the heart became affected, and streptococci were recovered from the blood. Death occurred three weeks after the operation on the shoulder. Post mortem: The larynx was still a little inflamed; the heart had large, green, recent vegetations on the tricuspid valves such as are usually found with pneumococcic infections. The heart's blood contained streptococci; the lungs showed recent pleurisy and septic infarcts; the spleen and the liver were both enlarged.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 19, 1912:

CHOLERA

ON THE CLINICAL RECOGNITION OF SYPHILITICS.*

BY WILLIAM W. GRAVES, M.D.,

ST. LOUIS, MO.

ASSISTANT PROFESSOR OF NEUROLOGY IN THE ST. LOUIS UNIVERSITY SCHOOL OF MEDICINE.

Wollen wir weiter kommen so müssen wir genauer untersuchen.—Rudolf Virchow.

SYPHILIS is a chronic infectious disease permeating all branches of society. Neither age, nor sex, nor social position, nor chastity renders one immune to this disease. It differs from all other infectious diseases in its duration, with possibly the single exception of leprosy. At any period in the life of the infected individual its manfestations may recur, and we are, therefore, unable to know its termination. Its symptomatology is as broad as special pathology. There is scarcely an organ or tissue in the body exempt from its manifestations. There are but few diseases which it may not simulate and none which it may not modify. It is rarely directly fatal, but its indirect mortality is believed to be very high—how high is as yet indeterminable. It lowers one's general resistance, thus predisposing to other diseases and often complicating them. No other disease is followed by such distressing sequelæ, chief among which are tabes and general paresis. Like another social disease, gonorrhea, the effects of syphilis are not confined to the infected individual. In the marital relation it is not infrequently communicated. Syphilis differs from all other infectious diseases in its effects upon the descendants of its victims. It is here that its most pernicious effects are wrought, pernicious in causing a frightfully high antenatal and postnatal mortality and in depriving the offspring of a healthy birthright.

Because syphilis is an infectious disease permeating all branches of society; because of its Protean manifestations and sequelæ: because it lowers the general resistance of the individual: because it simulates, modifies, predisposes to and complicates other diseases; because of its effects upon the immediate progeny and upon later generations, the recognition of the syphilitic is a matter which deeply concerns the infected individual, his descendants, the State and the physician. It is not within the scope of this communication to even touch upon the diagnosis of syphilis or of syphilogenous diseases, although that which is to follow will, I trust, be helpful in th recognition of some of the Pretean manifestations of the disease. My theme is the syphilitic and not syphilis.

*From the Department of Nervous and Mental Diseases. Alexian Brothers' Hospital, St. Louis (St. Louis University).

Since we have no means of knowing the termination of syphilis in any individual who has acquired it, all such individuals must be considered syphilitics. I have in other communications (33, 34, 35, 36, 37) pointed out the correlation of certain deviations, clinical signs and conditions, and certain methods of study which I believe will aid us in the clinical recognition of the so-called heredosyphilitic. In this communication I shall confine my remarks mainly to the clinical recognition of syphilitics in periods more or less remote from the time of infection and in such periods when they are usually considered free from active surface, visceral, nervous, or para manifestations; in other words, to the clinical recognition of syphilitics in the so-called latent periods of the disease.

Because syphilis is a chronic infectious disease, it will be here maintained that in the course of time it often brings about definite changes readily discernible through the employment of well-known methods of clinical investigation, and that these changes wrought by syphilis when found make up an assemblage of physical signs not correlated in other diseases, and hence may be designated *a syphilitic syndrome* and utilized in the clinical recognition of the syphilitic. Great progress has been made in recent years in medical knowledge which finds application in the recognition of the syphilitic. The finding of the *Treponema pallidum,* the determination of the Wassermann reaction in blood serum and spinal fluid, cytological studies, Nonne-Appelt and kindred reactions in the spinal fluid, and more recently the Noguchi luetin reaction, together make up an assemblage of laboratory findings unequaled in any other disease. Laboratory methods, however, can never supplant clinical observations and deductions; but they may and do furnish invaluable supplemental evidence and they further serve the purpose of checking and controlling our clinical methods. Laboratory methods must remain inert or at least fall short of their possibilities if in our clinical studies we fail to recognize the individual in whom these methods find application. The clinical recognition of the syphilitic is, therefore, more urgent at the present time than ever before because laboratory methods furnish increased possibilities in such recognition.

In this connection it cannot be too strongly emphasized that the presence of the Wassermann reaction alone is not conclusive evidence that the disease from which an individual may suffer is due to a syphilitic process. It shows merely that the individual in whom it is definitely found, when we can exclude other conditions which produce it, is a syphilitic. The presence of it, therefore, in any individual is a great aid in recognizing him as a syphilitic; but its absence in any individual in no sense justifies the conclusion that he is not a syphil-

itic because it is not constantly present in any period of the disease. Nevertheless, the Wassermann reaction has become indispensable in our studies of syphilis and the syphilitic, but it has its limitations. Any method or combination of methods utilized in diagnosis, without considering the whole individual, is apt at times to impede the recognition of disease. We have only to remember how the clinical recognition of pulmonary tuberculosis was impeded for a number of years following the discovery of the tubercle bacillus. The same danger confronts us now in the clinical recognition of syphilis and the syphilitic. Just as in former years we forgot how or rather failed to study the whole individual while searching for the tubercle bacillus, so now in the absence of a Wassermann reaction we are either apt to overlook manifest signs or to study inadequately the whole individual and thus fail to recognize his disease.

Recognizing the limitations of laboratory methods is to estimate them at their true worth. While great progress has been made in recent times in the recognition of syphilis and the syphilitic through the utilization of these methods, can we say the same for our purely clinical methods? Unquestionably, no! Since the epoch-making studies of A. Fournier, W. Erb, and others, by which the definite connection between syphilis and tabes has been established, and the studies by A. Fournier, Kraft-Ebbing, E. Mendel and others which have shown the definite connection between syphilis and general paresis, no decided advance has been made in the clinical recognition of the syphilitic. The reasons for this state of affairs are to be found in what appears to be the presence of inherent difficulties, and difficulties which must be reckoned with and overcome before we shall be able to keep pace with the laboratory methods and utilize them to the extent of their possibilities in our clinical studies. These difficulties are fundamental, have existed for years and are: First, our conceptions concerning the manifestations of syphilis in its acquired and so-called hereditary forms; second, our belief in its curability and our conceptions concerning its communicability; third, our methods of study.

1. Present conceptions concerning the manifestations of syphilis in its acquired and so-called hereditary forms: There is abundant evidence at hand indicating that the clinical recognition of the syphilitic is becoming, as time goes on, more and more difficult. It is apparent in the population of civilized countries where syphilis has long prevailed that the clinical history of syphilis is not what it formerly was and that the surface manifestations by which we have been so long accustomed to recognize the disease in any of its so-called stages are less pronounced than in former years. This fact is not recognized as generally as it should be even by those most interested in the problems of syphilis, and it finds no recognition whatever among the rank and file of the profession. The idea still generally prevails among the profession and almost without exception in the lay mind that syphilis is a skin disease. It is not generally recognized that surface manifestations, nowadays, even the initial lesion in some, may be wholly absent or at least so slight as to entirely escape the individual's attention. It is not generally recognized that in the vast majority of cases, nowadays, surface manifestations are extremely mild and are seldom followed by lasting marks. It is not generally recognized that so-called malignant syphilis, characterized by early cachexia, decided skin and bone manifestations, which was of such frequent occurrence several hundred years ago and is today of such frequent occurrence when syphilis invades a virgin soil, is relatively infrequent nowadays among syphilitics in populations where syphilis has long existed.

For general enlightenment along the line of the manifestations of syphilis in virgin soil, no article of recent years is deserving of closer study than that of Col. Lambkin[1] on the recent outbreak of syphilis in Uganda. Further evidence in support of the increasing mildness of surface manifestations in our population is apparent in the rarity with which are found marks of former lesions in tabetics, paretics, and individuals suffering from nervous and visceral syphilis. Additional convincing evidence may be deduced from the fact that not a few individuals suffering from the later manifestations of syphilis or from its sequelæ are entirely ignorant not only of the initial but of other lesions. Furthermore, it has long been recognized that females, as a rule, suffer less frequently from surface manifestations and sequelæ than males, and this fact should be remembered in our clinical study of females, particularly of the wives of syphilitics. The mildness of surface manifestations, nowadays, has been ascribed to a sort of racial immunity engendered by a gradual syphilization of the race. We must not conclude, however, that time brings with it an absolute racial immunity or even an attenuation of the virus. There is no evidence at hand indicating that visceral syphilis, syphilis of the nervous system, and parasyphilitic diseases are becoming either less frequent or less severe. Indeed, these affections are believed by many to be growing more frequent in our population. The assumed racial immunity, therefore, cannot be absolute and at most can be relative only, finding expression in many individuals of the race either in the absence or in the mildness of surface manifestations. May it not be that such relative immunity of many individuals to surface manifestations is more than balanced in them by an increased vulnerability to the effects of the virus upon their deeper structures and particularly upon their nervous and vascular systems?

From the foregoing it appears that a gradual syphilization of the race is indicated by the mildness in many and the absence in some of the surface manifestations; hence syphilitics are becoming constantly more difficult of recognition. It follows, therefore, that the generally accepted present-day conceptions of the surface manifestations of the disease represent fundamental difficulties in the clinical recognition of the syphilitic, and that neither the negative history nor the absence of surface signs warrant the exclusion of syphilis in any individual. If our conceptions require alteration concerning the manifestations of syphilis in its acquired forms, such alteration is far more needful in the so-called hereditary forms. In our efforts to recognize the syphilitic, we may often obtain valuable information by studying the progeny; because no other disease is so certainly transmissible to the offspring. Failing to find one or more of the well-recognized signs, chief among which are Hutchinson's teeth, other dental anomalies, interstitial keratitis, deafness without otitis, bone, joint, skin and mucous membrane affections, etc., etc., in the progeny, do we not as a profession

consider the progeny free from every sign of hereditary taint and thus either exclude syphilis in the parents or point to the progeny as living examples of the triumphs of our therapy in the parents?

2. Our belief in the curability of syphilis and our conceptions concerning its communicability: If there be any one thing the medical profession is united upon, it is the belief in the curability of syphilis, and this belief is one of the principal impediments to the clinical recognition of the syphilitic. Our attitude toward the marriage of syphilitics is, perhaps, the best evidence of our belief in our cures. "How soon may a syphilitic marry?" is a standard question in examinations of medical schools and medical examining boards. A prominent syphilographer recently lauding salvarsan expressed the belief that by its use the period of treatment might be shortened and that the marriage of the syphilitic might not be so long deferred.

Sir Johnathan Hutchinson[2] has said, in effect, that a male syphilitic is rarely capable of conveying the disease either to his wife or offspring pro-, vided he has remained continuously under treatment (Hutchinson's) for a period of two years; but, so far as I know, no other great authority is quite as sanguine either of the innocuousness of the syphilitic or the curability of his disease. Nevertheless, it is an almost universally accepted medical dogma that syphilis is not communicable in its later stages or in the absence of primary and so-called secondary lesions; hence medical authorities unanimously consent to the marriage of a syphilitic three, four and five years after infection, provided he has had rather continuous treatment during this time and has shown no recent manifestations. While we are, as a profession, optimistic in our belief in the curability of the disease, as is evidenced by our attitude toward the marriage of the syphilitic, we are pessimistic as to the future of the individual who fails to remain under rather constant treatment for three, four, or five years. Now it is safe to say that not more than 10 per cent. of the number of syphilitics who come under medical observation in the early periods of the disease receive what is believed to be adequate treatment; hence the number of adequately treated cases, even though such are cured, is insignificant and negligible in our clinical studies. The truth of the matter is that no man can say when a syphilitic is cured nor when he is no longer capable of conveying the disease either to his consort or his progeny; because clinical experience teaches that in any period of the life of the infected individual, incident to the lowering of general or local resistance or independently of the one or the other, manifestations may recur or appear and that, too, in some irrespective of either the manner or the length of treatment.

Furthermore, serological studies of the one-time-known-to-be infected individual, of his consort, and of his progeny, substantiate recent clinical experience in showing that a large percentage of supposedly adequately treated individuals have not been cured at all: that a relatively large percentage of wives of syphilitics are also syphilitic and that many of the progeny of syphilitic parents, even not a few of those free from the usually recognized signs of congenital syphilis, are likewise contaminated. But our belief in time and specifics blinds us to these clinical truths and is, therefore, a decided impediment to the recognition of the syphilitic and syphilogenous diseases. Believing in our cures and resting secure in the presence of apparent good health or in the absence of active or para manifestations, we come to regard the one-time-known-to-be syphilitic cured, and he is thereafter no longer the object of observation and study. If he is cured, then, certainly there is no danger to consort or progeny; and, if we look at these at all, unless we find the usually recognized gross manifestations, we construe the absence of such as evidence of the values of our therapeutic endeavors. Hence it is that our belief both in the triumphs of our therapy and the noncommunicability of the disease in certain periods are decided impediments in the clinical recognition of the syphilitic.

3. Our methods of study: If our conceptions of the manifestations of syphilis in its acquired and so-called hereditary forms have impeded the clinical recognition of syphilogenous diseases and the syphilitic; if our belief in our cures has blinded us to the more subtle manifestations of the disease in individuals and in parents and progeny, our methods of study have been even more serious handicaps in our clinical work. But our methods of study are dependent upon our conceptions of the manifestations of the disease, of its curability, and of its communicability. The existing conceptions in these matters have rendered our methods of study faulty, it seems to me, mainly in two directions: (a) In definitely excluding the disease in the absence of a positive history of initial and other lesions; (b) in failing to consider the whole individual in our clinical studies.

(a) Syphilis is the only disease we definitely exclude by a negative history, and it is the only disease we positively diagnose from a positive history, and in either case oftentimes without a careful study of the whole individual. It was the negative history of initial and other lesions in many paretics and tabetics supported by the infrequent findings in them of signs of former surface manifestations which prevented for so long a time the conception that either acquired or congenital lues was the underlying cause of these conditions, and the negative history and paucity of surface signs still prevent the universal acceptance of the dictum "Without syphilis, no paresis and no tabes." It is the negative history so common among syphilitics generally nowadays that prevents many practitioners from even considering the possibility of infection unless the individual shows active surface, visceral, nervous or para manifestations. "If I had ever had syphilis, I should know it," is a common exclamation of patients, and the medical mind still clinging to classical textbook descriptions of the so-called stages of the disease answers, "Of course you would," and from the negative history excludes even the possibility of infection. No clinical history is considered complete in an adult male without inquiry into its venereal aspects; and, although an individual may admit frequent exposure or even several attacks of gonorrhea, if he assures us he has never had a genital sore, eruptions of the skin or mucous surfaces, or falling of hair, syphilis is, as a rule, definitely excluded.

A few of us, remembering the possibility of extragenital and innocent infections and the frequency with which abortions occur in syphilitic families, and remembering, furthermore, that all patients are not truthful regarding venereal history, look at the exposed surfaces, palpate the

lymph glands, etc., make inquiry concerning abortions and the health of the wife and children, and all of these points being negative the disease is definitely excluded. But the individual consults us, let us say, for an ocular palsy, pain, a change in his mental state, perhaps, a definite psychosis, gastric disturbance, a jaundice, or perhaps symptoms pointing to aortic aneurysm, and we have a Wassermann reaction made and this, too, is negative; yet this individual may be a syphilitic!

If we admit that some individuals are not truthful about venereal experiences, then syphilis cannot be excluded by a negative history. If we admit that it is possible that some individuals do contract syphilis without ever thereafter noting initial or other lesions, then syphilis can never be excluded by a negative history. If we admit that even a few individuals have syphilis without permanent or even transient surface signs, then syphilis can neither be excluded by their absence nor by a negative history of them. If we admit that abortions do not always occur in syphilitic families, then a history of their absence does not exclude syphilis in either parent. If we admit that the Wassermann reaction or any other single laboratory test or clinical sign is not constantly present, then we cannot exclude syphilis by the absence of the one or the other. If we remember the great number of syphilitics in the world and the prevalence of syphilis among prostitutes, the most common source of infection; if we remember our lax sanitary regulations of the disease, the rarity of premarital chastity among males, the relative frequency of extragenital and innocent infections, then, it seems to me, that unless it can be shown that an individual has never in his life come in contact with his fellows, we cannot exclude syphilis in him by a negative history. But the individual may be a so-called heredosyphilitic and yet show none of the heretofore generally recognized signs of the disease, and here again negative history is valueless because it is unusual for the offspring to have knowledge of the syphilitic infections of parents. Neither can we place too much reliance upon the history of a former infection—the diagnosis may have been wrong.

How then may we clinically recognize the syphilitic? By considering each individual who seeks medical advice as a whole individual. The prevalence of syphilis in all branches of society, its Protean manifestations, the frequency with which it predisposes to, complicates and simulates other diseases, if for no other reasons, render the consideration of the whole individual imperative in our clinical work. It is much easier to decide (?) what is wrong from the complaints of the patient or his more prominent physical signs—to call it eyestrain, epilepsy, floating kidney, sacroiliac disease, gastritis, neurasthenia, hysteria, rheumatic ocular palsy, gastric neurosis, a functional heart disturbance, a muscular rheumatism, a neuralgia, a bilious attack, a vertigo, a gouty diathesis, a malaria, and so on without number, than to make a study of the whole individual. Such study takes time, and, strange to say, is often regarded as wholly unnecessary in this day of specialism and short cuts to diagnosis. If this is true, then our failure to study the whole individual may well be the most serious impediment in the clinical recognition of the syphilitic. By the study of the whole individual is usually implied all that we can learn from the family history, the personal history, the history of the present trouble, and a searching physical examination. Because syphilitic manifestations are not infrequently found in the consort and progeny of syphilitics, our clinicial conceptions of the whole individual must be enlarged so as to embrace a study of these. Just as it is impossible to exclude by a negative history and the absence of surface manifestations the presence of syphilis in the individual, so it is impossible to exclude it by the same means in consort and progeny. It is not sufficient to recognize syphilitic manifestations in the husband, the wife, or the child; but, finding such in any one of these, we must study every member of the family. In doing this, we shall be able to control by actual observation hearsay testimony which we have heretofore recorded as facts concerning family history and the health of the husband or the wife and the child.

I have elsewhere[37] called this method of study the comparative clinical studies of families. Such studies are of extreme value in the problems of heredity and in clinical medicine and are indispensable in our studies of the syphilitic. A consideration of the whole individual, as here defined and so enlarged as to embrace a study of every member of a family, will enable us to secure definite data from which the clinical recognition of the syphilitic will be made both more certain and more frequent than heretofore. Space prevents considering here, even briefly, the features of family histories common to syphilitic families; likewise the personal histories common to syphilitics. But there are certain subjective symptoms associated with definite physical signs which may be elicited and discerned in the vast majority of syphilitics during the so-called latent periods of the disease to which I must now direct attention, since the appreciation of these is fundamental to the clinical recognition of the syphilitic during such periods.

Such symptoms as malaise, indisposition, general bodily discomfort, pain, now here and now there, or definitely localized, physical and mental inadequacy, torpor, gastric disturbances, dizziness and in some slight elevations of temperature occurring usually six to twelve weeks following a syphilitic infection, are considered constitutional manifestations or the reaction of the whole organism to the spirochetal invasion. Such symptoms usually become less pronounced in a short time, whether the individual have treatment or not, the local manifestations, if any have occurred, disappear, and, as a rule, in course of time a relative degree of health returns. He, thereafter, considers himself cured if he has had what his physician believes to be adequate treatment or if his disease has not been recognized by himself or physician, he remains oblivious to it and in either case enters the so-called latent periods of the disease. In some individuals such periods develop very early; in some, very late; and in others, happily the few, not at all. It is usually considered that period in the life of the syphilitic when neither local, focal, nor para manifestations exist. Arbitrarily fixed, the so-called latent period begins, as a rule, two to five years after infection, and from the viewpoint of the clinician it ends with the life of the infected individual.

Careful inquiry into the personal histories of those known to be syphilitics during this period, even of those to whom we have given what we consider adequate treatment, will disclose in many

breaks in health which often can be best interpreted as recurrences of the constitutional manifestations of the virus. Of these constitutional symptoms occurring and recurring in the so-called latent periods of the disease as well as in the presence of active manifestations, as far as my observations go, the most prominent are pain, feelings of fatigue, gastric disturbance, dizziness, periods of mental and physical inadequacy, and inability to react normally to the stresses and strains of ordinary existence. It is particularly the occurrences and recurrences of the constitutional symptoms during the so-called latent periods of the disease which should cause us to seriously question the reality of such periods and never to lose sight of the constitutional nature and chronicity of the infection. All clinical evidence—the local, the focal, the para and the recurring constitutional manifestations—is in support of the idea that the virus once invading the tissues of the body, so long as it remains, never becomes wholly dormant—latent.

A period or periods of relative tolerance for the virus, meaning thereby an excellent, a fair, or a poor resistance of the whole or a part of the organism, but never an absolute resistance, seems to me to be a better conception, one more in accord with the clinical experience, the natural history of the disease, and the results of treatment than that of latency. Oppenheim has said, and repeatedly emphasized in his writings, that the chief characteristic of the nervous manifestations of syphilis is that of exacerbations and remissions and this observation holds good for most of its organic as well as for its functional manifestations. Furthermore, careful study of the personal histories of known-to-be syphilitics indicate that exacerbations and remissions are characteristic of the constitutional manifestations of the disease. The conception of a relative tolerance is, therefore, founded upon clinical experience, the course and the manifestations of the disease. The occurrences and recurrences in the constitutional manifestations during periods of relative tolerance are, doubtless, due to many factors, chief among which are the inherent resistances of the individual, his habits, his mode of life, and his environment. If the first factors (inherent resistances) are defective and from circumstance become more so, the disease may pass beyond our control. The other factors may in many cases be controlled and the first may often be improved by attending to the others so that a relative degree of health can be established in the vast majority of syphilitics. But our control in any one or in all of these factors is seldom absolute; hence, as a working clinical axiom it may be asserted that the individual who has contracted a syphilitic infection either *in utero* or after his birth remains thereafter one of lowered general resistance. Careful studies of the personal (medical) histories of syphilitics and their progeny will verify this assertion and but few exceptions will be found, provided we further study each individual as a whole. I must beg indulgence in attempting to emphasize the recurring constitutional manifestations of syphilis during periods of relative tolerance because my experience has shown that such manifestations are usually overlooked and misinterpreted in the absence of "specific" history and the more active manifestations of the disease.

When as a profession we shall seriously study the recurring constitutional manifestations of syphilis we shall find them to be by far its most frequent and most important manifestations. They are the most important because they represent the reactions of the organism to the virus—its struggle to establish a better tolerance and our recognition of them will often enable us to aid Nature in her efforts and thus prevent in some the more serious manifestations. The recurring manifestations may either be so slight or so evanescent or recur so infrequently as never to seriously interefere with the pursuits of the individual or to cause him to seek medical advice (excellent tolerance). When complained of, if at all, to the physician, they are referred to as undue susceptibiity to fatigue, pain in different parts of the body, rheumatism, bilious attacks, stomach trouble, etc. They are to be found among the minor ailments which we often fail to note or we consider them unimportant in working out personal (medical) histories. In not a few, however, the constitutional manifestations become very definite at variable periods of time following the infection (fair tolerance). In some they persist from the beginning (poor tolerance). In others after periods of apparent good health extending over a number of years, following some sudden or prolonged period of stress or strain or independently of such, constitutional manifestations become relatively constant, bringing about states of chronic invalidism characterized by mental and physical inadequacy, the chief complaints centering either about the gastrointestinal tract or the nervous system or both. My observations have shown that so-called neurasthenic and psychasthenic states, functional neuroses and psychoses, recurring or chronic states of mental and physical inadequacy owe their origin and perpetuation in part at least in not a few individuals to a chronic syphilitic intoxication acquired either *in utero* or after birth. It may be asked: Are the constitutional manifestations of syphilis occurring and recurring during the periods of relative tolerance sufficiently definite to enable us to recognize them as syphilitic manifestations? Unquestionably, no! Even the local and focal manifestations of syphilis, such as diplopia incident to a transient ocular palsy, an iritis, a choroiditis; definitely localized pain, such as a tic douloureux, an intercostal neuralgia, anginal attacks, Jacksonian seizures, bone, joint, lymph gland and surface manifestations, enlargement of the liver, spleen, etc., etc., are not sufficiently definite to enable us to recognize them as syphilitic in origin from the history alone. We may say, therefore, that neither the constitutional, the focal, nor the local manifestations of syphilis occurring alone or in combination during the periods of relative tolerance are sufficiently distinct to enable us from the history to definitely recognize them as syphilitic in origin. But they are sufficiently definite to cause us to make specific inquiry concerning them, to think of the possibility of syphilis in any individual presenting them, and to proceed with the study of the individual as a whole.

The conception of a syphilitic infection leading to a chronic intoxication, but with the resistances of the body so holding the virus in check as to establish periods of varying tolerance for it, affords a logical explanation for the recurring constitutional and other manifestations in many and likewise for the development in some of so-called para manifestations. If this conception is well founded we should expect to find evidence in support of

it in our physical examinations of syphilitics. This conception, therefore, *a priori* points to the development of physical signs originating in certain tissue reactions incident to the chronicity of the syphilitic infection. Now if such signs really exist, an appreciation of them should aid us in the clinical recognition of syphilitics.

Having pointed out some of the fundamental difficulties in this problem and having indicated both the necessity for and the manner of overcoming these difficulties in our clinical studies, let us now direct our attention to an assemblage of physical signs which my studies of recent years have shown to be common to syphilitics—signs developing in an insidious manner during their periods of relative tolerance. In contradistinction to the grosser manifestations of the disease they may be called its more subtle signs. They seem to originate in or to be dependent upon certain tissue reactions incident to the virus and to the chronicity of the infection. While scarcely an organ or tissue in the body is exempt from the manifestations of syphilis, certain structures have always seemed more vulnerable to the virus than others. Syphilis in this regard differs in no way from other infections. The syphilitic virus, undoubtedly, has elective affinities for certain structures. Formerly it was mainly the skin, the bones, the joints, etc.; but with a gradual syphilization of the race these structures seem to have made a relative gain in resistance, whereas the deeper structures of the body, and particularly the vascular and nervous systems, seem to have become more and more vulnerable. The virulency of the virus has, probably, remained the same; but the soil has changed with the years and likewise the manifestations of the disease. The more subtle signs of syphilis are founded upon this clinical assumption and in addition upon clinical and serological evidence that syphilis is a chronic infectious disease. The physical signs common to syphilitics, discernible during the periods of relative tolerance for the virus and here designated *A syndrome syphilitica*, are: (a) Those of a general nature; (b) those pertaining to the cardiovascular apparatus; (c) those pertaining to the nervous system.

(a) The syphilitic during his periods of relative tolerance who is free from intercurrent affections, upon superficial inspection usually passes for a well-nourished individual. Let us recall the apparently good nutritional states commonly noted even in tabetics and paretics often persisting until the conditions are far advanced. If, however, there is a family tendency to obesity or to thinness, these tendencies are apt to be accentuated in the syphilitic. Sir Jonathan Hutchinson has emphasized the characteristic of a syphilitic infection to accentuate the natural tendencies (weaknesses) in the individual, and this is aptly illustrated in the general nutritional states of syphilitics. A closer inspection of the syphilitic will frequently show that he wears only a mask of health, as is indicated by a degre of pallor which is often in striking contrast to his nutritional state. During the early periods of the disease the skin and visible mucous surfaces are often flushed, hyperemic; but in the course of time in many a degree of pallor indicative of disease becomes apparent. As we grow older we become paler. We lose the bloom of youth with advancing years. But if we are in health during the declining years (after forty) our pallor is, I may say, a healthy pallor and is in keeping with our years. It is the exceptional syphilitic who does not show a degree of pallor—an unhealthy pallor—beyond his years noticeable within from three to five years after his infection. This pallor is also common to the progeny of syphilitics, and as we shall later see, probably has in them the same foundations.

Syphilitics and their progney appear older than their years, not only because of the pallor often noticeable in them, but because of other signs, such as little telltale wrinkles about the brows and mouth and sides of neck, an old, settled, often dull look about the eyes, and with these signs of premature age are often associated the facial expressions of fatigue. In some syphilitics there is an added element to the pallor, a definite cachexia, which might be called a cachectic pallor. The pallor common to syphilitics and their progeny, even when cachectic, is peculiar in this, that it is seldom associated with a blood picture of anemia, and if so is rarely profound. Indeed, in not a few instances of extreme pallor, where from this alone one would strongly suspect a decided anemia, an actual increase in the red cells was found associated with good hemoglobin percentages. The pallor, or as I have called it, the cachectic pallor, is usually decided in paretics, and particularly so in tabetics, but not more so in them than in syphilitics who have only a fair, a poor or a failing tolerance for the virus. The skin surfaces about the body generally are usually pale, where not pigmented, and the skin is often in places dry, harsh, scurfy, and atrophic to a degree beyond the years. A clinicial fact well worthy of notice and possibly indicating one factor underlying the pallor without anemia, common to syphilitics, is its prompt amelioration in many and prompt disappearance in some for a time incident to specific treatment.

While the main characteristic of the face of a syphilitic is that of pallor, there is another in the pigmentation most frequently seen about the back and sides of neck, and occasionally about the forehead, other parts of the face and other parts of the body. Its occurrence independent of definite lesions, its permanency, its symmetry, and its tendency to conform to posterior nerve root distributions cause me to consider it here as a general sign of a syphilitic infection. About the neck it occurs, according to Shillitoe,[3] in two well-defined forms: (a) A well-marked band of pigmentation extending around the neck (collar of Venus) and noted by him seven times in thirty-seven cases; and (b) as leucodermic patches surrounded by a network of pigmentation noted by him thirty times in thirty-seven cases. Occurring about the forehead, the pigmentation is usually distributed irregularly, and is retiform like that most frequently to be observed about the neck. The great frequency of pigmentation about the neck in syphilitics at once establishes it as a sign of great worth in their clinical recognition. Situated as it usually is out of the direct line of vision of the patient or the physician, it is rarely complained of by the former or noted by the latter; hence it is that the so-called pigmentary syphilide, despite its occurrence in many syphilitics, still remains an unappreciated because unlooked for sign of syphilis. My observations have shown that in a few syphilitics the pigmentation is rather evenly distributed about the face and neck. But I have noted far more frequently than uniform pigmentation

in these locations and quite constantly associated with irregular pigmentation about the back and sides of neck the presence of uniform pigmentations occurring about the orbits and mouth. Occurring about the orbits, it is often sharply limited to the oculoorbital folds and the upper lids; and about the mouth it is often confined to the skin surfaces of the lower lip. The skin surfaces about the orbits and mouth show shades in brown and yellow, their intensity depending upon the normal tints of the skin peculiar to the individual. In those cases where these pigmentations are present about the orbits and mouth and when associated with pallor of the lips and intervening skin, the expression often takes on a grotesque appearance.

However specific a pigmentation may appear to be, it must not be forgotten that pigmentations occur in other diseases than syphilis, such as hyperthyroidism, Addison's disease, arsenic poisoning, diabetes, etc.; but the character of the pigmentation and its distribution in these conditions will usually enable one to make the differentiation.

(b) Pallor without anemia and other signs of premature age so frequently to be observed in syphilitics and their progeny should cause us to direct our attention to the cardiovascular apparatus which, probably more than any other, bears the brunt of a syphilitic infection. No other disease or condition known to have intensive vascular reactions has such a chronic course and at the same time is so frequent in all ranks of society. Therefore, if syphilis has a deleterious effect upon the vascular system, both its chronicity and universality should render it a frequent cause of cardiovascular disease. "The most important form of infectious disease of the vessels is that due to syphilis" (Benda).[4] "Of the acute infectious diseases, syphilis is the one which has a special predilection for the arteries" (Osler).[5] "Upon no system does the virus of the disease fall with greater intensity in all stages than upon the blood vessels. It is safe to say that through the arteries syphilis kills more than through any other channel. Cerebrospinal lues is largely a matter of arterial disease" (Osler and Churchman).[6] "No disease is, probably, more productive of arterial degeneration than syphilis. . . . Although syphilis may attack any of the arteries, it has a predilection for the vessels at the base of the brain" (Mott).[7]

It is the intimate association of the vascular apparatus with every part of the body which renders it constantly exposed to the syphilitic virus throughout the course of the disease. That the vascular system is peculiarly susceptible to the effects of syphilis or its toxins is shown by the general hyperemia observed during the early periods of the disease, by the local reactions of the vessels adjacent to and within initial scleroses and other early and late lesions, by the great frequency with which the aorta and pulmonary arteries show specific reactions (mesarteritis) in both the acquired and congenital disease (Chiari,[8] Benda,[4] Wiesner,[9] Bruhns,[10] and Rach and Wiesner[11]), by the relative frequency of aortic aneurysm and so-called varicose ulcerations in syphilitics, by the relative frequency of cardiac and vascular changes to be noted both clinically (Strümpel)[12] and anatomically (Frankel)[13] in tabetics and paretics, and by the relative frequency with which organic nervous disease occurs incident to or associated with disease of the vessels of the nervous system in syphilitics and congenital syphilitics (Heubner,[14] Nonne,[15] Rumpf, and many others). Syphilis might, therefore, well be called a vascular disease since so much of its pathology is connected with its vascular manifestations. Such a conception of syphilis, if generally adopted, would go a long way toward removing the disease from among the dermatoses and placing it among the internal diseases where it rightly belongs, and thus lead to a more frequent recognition of the syphilitic by the clinician. But so much emphasis has been placed upon the so-called specific vascular changes (endarteritis, mesarteritis) in syphilitics and the predilection of the virus for the vessels of the nervous system and the aorta that in the absence of clinical signs pointing to the involvement of the one or the other, syphilis as the cause of general arterial disease is rarely given due consideration by either the pathologist or the clinician.

If syphilis is a common cause of general vascular disease, we should expect to find clinical evidence of it in the majority of syphilitics before the age of forty because it is an established fact that syphilitic infections occur most frequently in the relatively young, *i.e.* between the fifteenth and thirtieth years of life. "My experience shows that arteriosclerosis is found with unusual frequency in young persons, the subjects of syphilitic infection" (Mott, "A System of Syphilis," Vol. 4, page 49). But we seldom think of the possibility of arteriosclerosis before the fortieth year of life; and, finding it in earlier periods, readily attribute its presence to other causes, such as concomitant cardiac or renal disease, overwork, overeating, the diatheses, as the gouty, the rheumatic, etc., other infections or intoxications, or hereditary predisposition. Finding it after the fortieth year of life, we readily account for its presence by age, and if the degree is out of all proportion to the years of the individual either before or after the fortieth year, we usually account for it by one or more of the factors just mentioned. Hence the so-called specificity of arterial disease in syphilitics, the supposed predilection of the virus or its toxins for the vessels of the nervous system and the aorta, the age at which arterial changes naturally occur, and the other factors known to bring about arterial changes have prevented physicians generally from thinking of syphilis as a frequent cause of diffuse vascular disease and utilizing the presence of such findings in the clinical recognition of the syphilitic. Remembering the intensity of the vascular reactions of the aorta and other large vessels and the vessels of the nervous system in the few, the chronicity of the disease and the continuity of the vascular apparatus should cause us to expect the involvement of the peripheral vessels as well in many syphilitics. It would, indeed, be an inexplicable circumstance and one without parallel among the various diseases and factors causing arteriosclerosis if the vascular changes due to syphilis were confined exclusively to the vessels of the nervous system, to the aorta and other large vessels.

My observations in syphilitics during their periods of relative tolerance for the virus have shown the great frequency among them of clinical signs indicative of diffuse vascular changes. Furthermore, my studies have shown the great frequency of such signs in the progeny of syphilitics, even in those having none of the heretofore generally recognized signs of congenital syphilis. I have elsewhere[33] referred to vascular disease as the connecting thread between the syphilitic and

his progeny. My studies have shown that it is the exceptional syphilitic, unless he has had early and persistent treatment, who will fail to disclose a degree of vascular changes beyond his years within the first five years after his infection and, furthermore, that it is the exceptional individual born of syphilitic parents who will fail to show some signs of vascular disease as early as the tenth year of life. Syphilitic vascular disease is, probably, one cause of the frightful antenatal and postnatal mortality among the progeny of syphilitics, and, probably, the main cause of their abiotic natures, their proneness to disease and their lessened expectancy in life, and it is, probably, the main cause of the lowered general resistance in many individuals who have acquired syphilis. My comparative clinical studies of syphilitic families have not infrequently revealed a greater degree of vascular disease in the adolescent members than in either parent. Comparative clinical studies of families will not only enable us to differentiate between the various factors and that of syphilis causing arterial changes, but will also enable us to utilize the presence of such changes in the clinical recognition of both the syphilitic and his progeny. Such studies may be further utilized in showing the etiology of the so-called hereditary predisposition to arterial degenerations and that of juvenile arteriosclerosis, the frequency of which latter condition was first emphasized by Romberg[16] in 1904. Remlinger[17] in 1905, reviewing Romberg's juvenile cases, says: "Concerning the cause of so-called diffuse arteriosclerosis in the young, nothing is known." Rach and Wiesner,[31] who have recently shown the great frequency (59 per cent. of their cases) of changes of the larger vessels in premature and newborn congenital syphilitics suggest the possibility of similar changes in the peripheral vessels as an underlying cause of juvenile arteriosclerosis. Moreover, the frequency with which I have been able to find clinical evidence of arterial changes in the progeny of syphilitics caused me in another place[34] to make the deduction that many of such progeny are born with a degree of vascular disease. My studies made in a comparative clinical way indicate that both hereditary predisposition and Romberg's juvenile arteriosclerosis may not infrequently be traced either to syphilis in the parents or to syphilis in the more remote ascendants. Space forbids my considering here the cardiac manifestations of syphilis, but I may recall the fact that recent serological observations have shown that aortic valvular disease, particularly with regurgitation, is almost if not quite as frequently due to a syphilitic infection as is aortic aneurysm. The presence of a degree of arteriosclerosis beyond the years of the individual cannot always be ascribed to syphilis. Just as we differentiate between the various causes of fever, so must we differentiate between the various causes of vascular disease. Comparative clinical studies of families will often aid us in such differentiation.

Osler has said that it requires not only experience but education to found correct judgments of the arteries. It seems to me that the first step in this direction is to think of the possibility of clinical signs of arterial changes as occurring in any period of life, and the second is to bring to bear in our investigations every means that may aid us in discerning them. Holding fast to the clinical fact that syphilis may be a frequent cause of diffuse vascular disease, let me recall the signs which we ordinarily interpret as indicative of arteriosclerosis and direct your attention to some other signs not so well known and appreciated. Clinical evidence of arteriosclerosis is usually considered ample when two or more of the following findings are demonstrable: Undue palpability of radials and other vessels; undue visible pulsation in brachials, temporals, and other vessels, and undue tortuosity in these; alterations in second heart sounds, especially the aortic, and the determination of the relative size and functional worth of the heart muscle. To these is usually added an estimation of arterial tension with a suitable apparatus though it is of but little value in determining the presence of arteriosclerosis, especially in the relatively young. Ophthalmoscopic studies of the retinal vessels often afford valuable evidence of arteriosclerosis. Perhaps the most important of the usual signs are undue palpability, visible tortuosity, and pulsation of arteries. A detailed description of the methods employed in studying the cardiovascular apparatus would be superfluous here; but the palpation of vessels is such an important procedure in determining the presence of arterial changes that I may be pardoned for calling attention to the necessity of accurate technique even in the frequent and time-honored practice of feeling the pulse.

A moderate sized artery, such as the temporal or radial, when neither thickened nor in a state of spasm, is felt to collapse under increasing finger tip pressure and it is with difficulty differentiated from adjacent structures. When such a vessel is thickened and sclerosed the wall remains more round, the finger tip glides over its rounded surface, and one feels a degree of resistance not present in normal arteries. Sclerosing arteries are frequently unduly tender to firm finger tip pressure, far more so than the adjacent structures, a fact which I have frequently observed in the various periods of syphilis as well as in other conditions associated with arteritis. Wertheim-Salomonson[32] has recently called attention to the value of finger nail palpation of arterial walls, and I can attest the great value of this method when associated with the method of finger tip palpation.

Pallor is one of the signs of advancing years, and is doubtless mainly due in the old to structural changes in the peripheral vessels. Pallor may, therefore, be a sign of arteriosclerosis. Occurring at any period in life, when we can exclude other conditions producing it, such as anemia, nephritis, etc., it becomes a sign of vascular disturbance of great worth. I have already referred to the frequency with which a degree of pallor beyond the years of the individual is encountered in syphilitics and in their progeny, and in such it is usually associated with signs of arteriosclerosis. There are not a few syphilitics, however, who while showing pallor fail to disclose decided evidence of vascular disease or at least a degree of it sufficient to account for the degree of pallor. In such cases we must assume an abnormal degree of contraction (spasm) of the peripheral vessels. That an abnormal degree of spasm is one factor underlying pallor in such cases, as well as in syphilitics showing decided signs of vascular disease, is shown by the prompt disappearance of pallor in some and its decided amelioration in others under specific treatment.

A sign of arteriosclerosis almost constantly present in the old and frequently in the healthiest of us in some degree as early as the thirty-fifth year

of life is that which I have elsewhere[34] described as varnished scleræ. Its chief characteristics are: First, a shiny, glistening, and undulating appearance of the conjunctivæ overlying the sclerotics; second, undue tortuosity and prominence of the conjunctival and episcleral vessels with now and then punctate hemorrages into the conjunctival and episcleral tissues. The presence or absence of varnished scleræ may be easily determined by drawing down the lower lids while the patient is facing the light and directing his gaze upward. In such position one may readily appreciate the appearance of the scleræ and conjunctivæ, their tints, gloss, smoothness, or undulations, and the degree of tortuosity and prominence of the visible vessels. When this sign is well marked the prominent and markedly tortuous vessels seem to lie upon rather than within the conjunctival tissue. Syphilitics and their progeny show this sign with great constancy. The study of the conjunctival and episcleral vessels with the Czapski binocular corneal microscope affords ready means of detecting the earliest changes in these vessels and of getting further corroborative evidence of diffuse vascular disease. Dr. W. H. Luedde[18] has modified this instrument by providing a better illumination and thus enabling a greater magnification. He was the first to systematically employ it in the study of the sclerotic changes of the conjunctival and episcleral vessels. He has called attention to the peculiar oscillatory flow of the blood stream in these vessels without reference to the pulse rate and to the aneurysmal dilatations, the thickening and crinkling of the walls of these vessels in individuals showing clinical evidence of arteriosclerosis. He has even noted the presence of thickening and aneurysmal dilatations in nursing infants. In not a few cases of children and adults studied conjointly with Dr. Luedde in whom pallor and varnished scleræ were the most definite signs of arterial disease, and in many cases in similar periods of life showing in addition gross evidence of arterial disease this instrument in the hands of Dr. Luedde disclosed the changes just mentioned. The constancy with which the conjunctival and episcleral vessels show naked eye changes and the confirmation of such changes with Luedde's modification of the Czapski binocular corneal microscope should cause us to give these vessels routine consideration in our clinical studies of arterial disease.

(c) "The active principle of syphilis which is a poison for the whole system is especially a poison for the nervous system" (A. Fournier).[19] Ranking in constancy with the signs of vascular disease are those signs indicative of a syphilitic infection discernible by a clinical investigation of the nervous system. But the routine examination of the nervous system is an unusual procedure by many physicians in the absence of gross manifestations indicative of its diseases. It cannot be too strongly emphasized that no physical examination is to be considered complete without an investigation of the nervous system in its mental, motor, vasomotor, trophic, reflex, sensory, and sensorial spheres. In doing this we shall often find unmistakable signs of a luetic infection. Of these signs indicative of a leutic infection I shall consider here some pupillary, reflex, and sensory alterations, and only the more constant of these. In further communications I shall furnish data on the frequency of pupillary, reflex, and sensory alterations as well as on the other more subtle signs of syphilis already referred to in this paper, as occurring during the so-called latent periods of the disease. It is sufficient here to call attention to the presence of some of these signs during these periods and to define what is implied by alterations in (1) pupils, (2) sensation, and (3) reflexes.

(1)Alterations in pupils. With negligible exceptions (trauma, tumor, drugs, etc.) the Argyll-Robertson pupil, thanks to the work of Erb,[20] Gowers,[21] Uhthoff,[23] Oppenheim,[22] Nonne,[15] Bumpke,[42] Weiller,[25] Babinski,[26] and others, is now universally considered a sign of tabes, paresis, or syphilis. The A-R pupil is believed to be seldom of sudden occurrence, and that it is almost invariably preceded by sluggish pupillary reactions either to consensual or direct light stimulation, or both. Associated with both sluggish pupillary reactions to light and complete A-R pupils are two other signs; namely, asymmetry in pupillary form and differences in size. So constant is this association that it is unusual to find either sluggish or complete A-R pupils which do not show inequalities or asymmetries, or both. But pupillary inequalties and asymmetries occur with great frequency among syphilitics independently of sluggishly reacting and A-R pupils. My observations are fully in accord with those of Dufour,[27] Joffry and Schramek,[28] Piltz,[29] Babinski,[26] and others in regarding transient and permanent pupillary inequalities and asymmetries of the greatest diagnostic importance. A sign of relative frequency occurring either with or without A-R pupils is the abnormally small pinhead pupils—Erb's spinal miosis. When we can exclude other etiology (anomalous development, synichiæ, etc.) for such signs then their frequent association with sluggishly reacting and A-R pupils justifies the assumption of a common causation and likewise their clinical interpretation as signs of a syphilitic infection.

(2). Sensory alterations. My observations indicate that feelings of fatigue, transient and recurring pain about neck, knees, hip and shoulder girdles, crampy sensations in muscles and parasthesiæ in various parts of the body are frequent complaints of syphilitics during the so-called latent periods and that either hyperesthesia or sensory loss, especially the latter, is discernible with relative frequency during the secondary and with great frequency during the so-called latent periods of the disease. A. Fournier in his "Leçons cliniques sur la syphilis" seems to have been the first to recognize objective sensory disturbance in the secondary periods of syphilis. He states that it occurs rather frequently during these periods in the form of analgesia or associated with anesthesia but that he had not seen anesthesia without analgesia; that the temperature sense is occasionally and the muscle sense exceptionally impaired; that the analgesia varies in degree and distribution at times involving the greater surfaces; that it is usually symmetrical, occurs in islands, patches, most frequently about the upper and lower extremities and often about the dorsal surfaces of the hands and about the breasts and that it disappears with the secondaries under treatment. These splendid observations of Fournier seem to have been wholly neglected by syphilographers and clinicians, and so far as I know, by no other author considered a part of the symptomatology of secondary syphilis. My observations are entirely in

accord with those of Fournier as to the predominating character of the sensory disturbances (hyp- and analgesia) during the secondary periods of the disease. But I have found that similar sensory disturbances occur with great frequency during the so-called latent periods of the disease. It is now universally recognized that hypalgesia and analgesia, both more or less diffuse and in patches but conforming to nerve root distribution, are among the earliest sensory findings in tabes and that disturbances in other qualities in sensation are usually of later development. Accumulated neurological observations on the sensory loss in tabes and general paresis is wholly in accord with Fournier's observations in the secondary and with my own in the so-called latent periods of syphilis; namely, that sensory loss in other qualities does not occur as a rule without loss to pain. Moreover, this is a rule having but few exceptions in organic disease of whatever causation. The practical application of this rule to sensory examinations is obvious. When, let us say, only tactile sensibility is tested, as is so often the case in clinical work, diminution or loss to painful stimuli will be entirely overlooked.

My studies indicate that the examination of the entire surface of the body will disclose in many so-called latent syphilitics sensory loss to painful stimuli in the same zones commonly recognized as occurring in tabetics and that similar sensory disturbance will often be found in the same regions in which latent syphilitics so frequently complain of transient and recurring pain, *i.e.* about the neck, particularly in C2 and C3; about the shoulder girdle, particularly in C4, C5 and C8, D1 and D2; about the hip girdle, particularly in D12, L1 and L2 and about the outer surface of the knees and legs, particularly in L5 and S1. The frequency with which one may find hypalgesia and analgesia independently of other sensory loss in the secondary and so-called latent periods of syphilis suggests the idea that the virus of syphilis may have a special affinity for the pain conducting or perceiving mechanisms. Remembering the few syphilitics who receive adequate treatment, it seems possible that the sensory loss noted by Fournier in the secondary stages may persist in the many and that sensory examinations might be of service in diagnosis in the early stages of syphilis in those cases characterized by delayed, abortive or absent secondaries. Hypalgesia and analgesia in so-called latent syphilitics often but not always disappear under treatment; whereas in tabetics, as a rule, they remain fixed—permanent. Surface hyperesthesia is occasionally observed in so-called latent syphilitics, but just as in early tabes it usually occurs in patches in juxtaposition to the patches of hyp- and analgesia. Furthermore, in very early tabes and in so-called latent syphilitics, the muscles are often unduly tender and the mechanical irritability of peripheral nerves is not infrequently increased.

Alterations in reflexes: Physiological experiment and clinical observation have shown that the reflex activities of the organism are increased and diminished by whatever increases and diminishes the activity of the central nervous system. Any condition or disease which affects the organism as a whole or the nervous system in particular is usually manifested by alterations in reflex activities. We possess no single means whereby we may so definitely discern general perturbation of the whole organism and at the same time differentiate between health and disease as that afforded by investigating the more constant physiological reflexes. Therefore the testing of each of these should be made a part of every physical examination. The more constant physiological reflexes which may readily be tested are the superficial (skin) reflexes, (1) abdominal, (2) cremasteric, (3) sole, and the deep (tendon and periosteal) reflexes. The last include the knee jerk, the Achilles jerk, the homo- and contralateral hip adductor, the triceps, the biceps, the radial, and the ulnar triceps of Bechterew. Reflex activities fluctuate within wide limits even in healthy individuals, the fluctuation depending upon age, occupation, habits, exercise, rest, etc., so that in considering reflex alterations as signs of disease these and similar factors must ever be kept in mind. Pathological alteration in these physiological reflexes may consist in exaggeration, in inequality, in diminution, in abolition, in disproportion and dissociation.

Dissociation in reflex activity exists when, for example, tendon reflexes are present and skin reflexes are absent or the reverse; disproportion, when either superficial or deep reflexes are relatively more active in one part of the body than in another; diminution, when a reflex is not readily obtained or is still weak when a maximum of stimulation produces a minimum reaction and when controlled by the well-known methods of reinforcement; abolition, when maximum stimulation controlled by all methods of reinforcement fail to elicit the reflex; inequality, when difference is noted in a given reflex between right and left; and exaggeration in reflex activities exists when minimum stimulation produces maximum reactions when the reflexogenous zone of a given reflex is broadened and when associated response occurs in muscles not ordinarily affected by the stimulus.

In addition to the alterations in the physiological reflexes as signs of disease there are other reflexes not occurring in health the presence of which is universally considered signs of organic nervous disease; such as the Babinski, the Oppenheim, the Gordon and Chaddock reflexes commonly referred to as pathological toe reflexes. The interpretation of pathological alterations in the physiological reflexes would, indeed, be an easy matter if they occurred only in association with such signs of organic nervous disease as pathological toe reflexes, rigidities, clonus, motor weakness, tremor, ataxia, and Rombergism; but pathological alterations in the physiological reflexes occur independently of the signs of organic disease just mentioned. Since they do occur independently and since, if neither anomalous nor incident to local conditions, they are signs of disease they must receive consideration and if possible interpretation. The most frequent alteration within the limitations of health and occurring in what we call functional nervous disease and in arteriosclerosis, hyperthyroidism, alcoholism, etc., is that of equal exaggeration, particularly in tendon and periosteal reflexes. Therefore, some line of demarcation at which the pathological begins and the physiological ends is urgently needed by clinicians. In an article by Koloman Keller[30] appearing in 1909 and that of A. Myerson[31] soon to appear this long-felt want receives consideration. Keller studying the homo- and contralateral hip adductor reflexes has gone a long way toward establishing the limitations between

the physiological and the pathological exaggeration of tendon and periosteal reflexes of the lower extremities. Myerson in studying the same reflexes independently of Keller and in addition others not hitherto described, as well as the reflexes of the upper extremities of normal individuals, and comparing his findings in these with the findings in clinical material, mainly in my service at the Alexian Brothers' Hospital, has accomplished the same result for the whole individual. The definition of pathological exaggeration in physiological reflexes given above receives amplification in the articles just mentioned.

One classical sign of tabes is the absence of the knee or Achilles jerk; but studies of preataxic tabes permits the inference that abolition is preceded by diminution and this in turn by exaggeration in tendon and periosteal reflexes. Strümpel has suggested that there is, probably, a period in tabes in which the tendon reflexes are exaggerated. Evidence of this view is to be found in cases of lumbosacral tabes, in which Achilles jerks are greatly diminished or absent, with markedly increased knee jerks or the reverse and in cases where either knee or Achilles jerks are absent. In either case tendon and periosteal reflexes of the upper extremities are often unduly active. As far as my experience goes, the most frequent alterations in physiological reflexes in so-called latent syphilitics are equal and unequal exaggeration, disproportion, and dissociation; while equal and unequal diminution and complete abolition occur less frequently. When one or more of these alterations are found independently of the signs of organic nervous disease before mentioned, in an individual whose medical history and physical state reveal no data to account for them, then the possibility of manifestations of the syphilitic virus should be seriously considered. The clinical recognition of such an individual as a syphilitic borders on a certainty when one or more of the alterations in the physiological reflexes are associated with two or more of the pupillary or sensory alterations before mentioned.

The similarity in the alterations in pupils, sensation and reflexes in the early and so-called latent periods of syphilis, in preataxic tabes and in early paresis is so striking that one may well ask: In what way may these alterations occurring in latent syphilitics be differentiated from similar alterations occurring in paretics and tabetics? The differentiation is not always possible but the degree and the permanence of pupillary, reflex, and sensory alterations, the clinical history and the accompanying symptoms and physical signs are points for consideration. After all, the differentiation is not unlike that between the early and late manifestations of the same disease, a wholly unnecessary differentiation in the clinical recognition of the individual as a syphilitic. That some alterations in pupils, sensation, and reflexes are common to the secondary and so-called latent periods of syphilis, paresis and tabes, differing, if at all, merely in degree and in permanence, establishes beyond question their common foundation and justifies their clinical interpretation as physical signs of syphilis and their utilization in the clinical recognition of the syphilitic. These alterations in pupils, sensation, and reflexes have been so universally regarded as the basic signs of paresis and tabes that we have often failed to look for them except in those cases whose clinical histories pointed to these conditions. In this connection it is well to remember that statistical studies indicate that not more than 5 per cent of syphilitics become either tabetic or paretic. The great number of syphilitics who are either relatively healthy or who are suffering from so-called functional neuroses or psychoses or from various internal disturbances and diseases, in whom alterations in pupils or sensation or reflexes are found, for which other causation than syphilis can be definitely excluded, should cause us to regard these alterations as signs of a syphilitic infection. Therefore, if these alterations occur in other syphilitics than in paretics and tabetics, then their appreciation as physical signs of syphilis will go a long way toward the certain clinical recognition of syphilitics who are neither paretic nor tabetic.

Finally, *an appreciation of the whole individual* in connection with recurring constitutional manifestations; with pallor and vascular changes to a degree out of all proportion to the years and nutritional state of the individual; with pigmentations and with alterations in pupils; sensation, and reflexes will, I believe, place *the clinical recognition of so-called latent syphilitics*, like that of tabetics and paretics, among the certainties of clinical medicine.

THE IMPORTANCE OF HISTORY IN THE DIAGNOSIS OF INCIPIENT TUBERCULOSIS.

By JOHN M. CRUICE, A.B., M.D.,

PHILADELPHIA.

PHYSICIAN TO THE HENRY PHIPPS INSTITUTE OF THE UNIVERSITY OF PENNSYLVANIA, THE WHITE HAVEN SANATORIUM AND TO THE OUT-PATIENT DEPARTMENT OF ST. AGNES' HOSPITAL; INSTRUCTOR IN MEDICINE AT THE UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Much has been written upon the diagnosis of incipient tuberculosis, and in many articles great stress has been laid upon the importance of taking a careful detailed history of the case, and of properly interpreting the facts when obtained. But from my experience with the type of case we receive at the White Haven Sanatorium classified as incipient tuberculosis, and from the cases who have been treated for months and then come to the Phipps Institute to find out if they have tuberculosis, I am sure there are many whose lives will be saved if the practitioner be more alert and give more attention to the history of the case.

It is wrong, when one obtains a history more or less typical of tuberculosis which cannot be accounted for by some other pathological condition, simply because one is unable to elicit physical signs of the lesion, to assure the patient that he has no tuberculosis and permit him to go on his way rejoicing. The case should be watched and studied most carefully, repeated examinations should be made, and no trouble spared to clear up the diagnosis; it is so important for the future welfare of the patient that the diagnosis should be made as early as possible. If more attention were paid to the history of the case, and the profession at large were less timorous about making a diagnosis of tuberculosis, I am sure there would be more cases recovering from and fewer developing tuberculosis.

In going over the case records of the Phipps Institute I was greatly impressed with the number of cases who seemed to me to have typical histories of tuberculosis, that were diagnosed either non-tuberculous or some other condition. I thought it might be instructive, and I knew it would be interesting, to try to investigate the present condition of these cases. For this investigation I took all the cases coming to the Institute from January 1, 1907, to February 1, 1908, that were not diagnosed tuberculous. No attention was paid to whether their histories were suggestive or not of tuberculosis. In all there were one hundred and sixty-three cases.

Letters, inquiring as to their state of health, were sent out to these one hundred and sixty-three cases, each letter containing a stamped directed envelope and a blank as follows:

"Replying to your request for information about ....., I would report that this patient is .....

"Very truly yours,"

These letters were sent out principally to locate, if possible, the present whereabouts of the patient and to obtain what information we could concerning them. As the class of patients were of the poorest, I did not expect to get very large returns. Sixty-five letters were returned by the post-office as unable to be located. Of the remaining ninety-eight I was able to get definite reliable information about only fifty.

Of these fifty cases I personally examined thirty, five returned to the dispensary and were definitely diagnosed tuberculous, definite information was given at the Institute about three, the record of the death of four was obtained at City Hall, the records of other hospitals (Children's Hospital and White Haven Sanatorium) gave information about three, the death of three was reported by letter, the death of one was reported by a nurse from the Phipps Institute who helped me to investigate, and the condition of one child was reported by the doctor in attendance.

Sixteen of these fifty cases can be said to be non-tuberculous, twenty-three are undoubtedly tuberculous and eleven have died, four of these eleven having died of tuberculosis. The remaining seven died of the following causes: Asthma, 2; cancer of stomach, 1; perforated typhoid ulcer, 1; pneumonia, 1; whooping cough, 1; unknown cause, 1.

In two of these eleven cases, one dying of tuberculosis and one dying of whooping cough, there is reason to doubt the diagnosis on the death certificate. The one dying of tuberculosis, a colored man, aged thirty-one, who gave a history of pain in chest for a year, dyspnea on exertion, a few night sweats, edema of feet and loss of weight, when examined at the Institute was found to have all the signs of mitral stenosis and regurgitation and no sign of tuberculosis. As mitral stenosis is not infrequently diagnosed tuberculosis it is only fair to allow that the ultimate diagnosis is open to doubt. On the other hand the case supposed to have died of whooping cough was a woman of thirty years of age whose condition was diagnosed at the Institute as asthma and bronchitis, notwithstanding a history of direct exposure, previous attack of pleurisy, cough for five years with considerable yellowish white sputum, hemorrhage from the lungs, dyspnea on least exertion, poor appetite, gastric disturbance, occasional night sweats, edema of legs and face, suppressed menses, leucorrhea, loss of forty-four pounds in weight in a year and a half, and temperature as high as 100.8. The chest was full of râles with slight impairment marked over right upper lobe. Fifteen months after these facts were obtained at the Institute she is said to have died of whooping cough!

So we have twenty-seven out of fifty cases, diagnosed four or five years ago non-tuberculous, who have either died of the disease or have at present undoubtedly tuberculosis. When we remember that these diagnoses were made by men more or less trained in tuberculosis, who were examining the patients especially for that condition, but who from the fact that they could elicit no physical signs, were unable or unwilling to make a diagnosis of tuberculosis, I think it emphasizes very markedly the importance that should be given to the history of a case in making a diagnosis.

The sixteen non-tuberculous cases were diagnosed in 1907 as follows: Non-tuberculous, 5; normal, 3; pertussis, 1; adenitis, 1; imperfect metabolism, 1; neurasthenia, 1; chronic gastritis and anemia, 1; chronic pharyngitis and tonsillitis, 1; pleuritis, 1;

emphysema and bronchitis, 1. The twenty-three tuberculous cases were diagnosed as follows: Non-tuberculous, 10; bronchitis, 4; acute bronchitis, 2; chronic bronchitis, 1; adenoids, rhinitis, subacute bronchitis, 1; adenoids, 2; hepatic calculi, 1; slight pleural thickening, 1; asthma, 1. The four cases dying of tuberculosis were diagnosed as follows: Mitral stenosis and regurgitation, 1; enlarged tonsils and adenoids, 1; muscular rheumatism, 1; pregnancy, 1. The other seven cases that died were diagnosed as follows: Asthma and bronchitis, 1; asthma and deflected nasal septum, 1; bronchitis, 1; mitral stenosis and regurgitation and chronic pleurisy, 1; emphysema, 1; emphysema and chronic bronchitis, 1; non-tuberculous, 1.

In analyzing the histories of these fifty cases, I shall divide them into two groups: Group A, the twenty-three who are now tuberculous and the four who died of tuberculosis; and Group B, the sixteen who are non-tuberculous and the seven that died of other causes than tuberculosis.

In Group A there was a history of direct exposure to tuberculosis in fourteen cases, no exposure in eleven cases and no record in two cases; in Group B a history of direct exposure in eight cases, no exposure in fourteen and no record in one case. In other words, in Group A there was a history of exposure in fifty-six per cent. of the recorded cases in comparison to thirty-six and three-tenths per cent. of the recorded cases of Group B.

This history of exposure should be gone into very thoroughly, because if obtained, it is a most valuable aid to diagnosis; and as Norris has put it, "It will not do merely to inquire if any of his immediate family have died of tuberculosis and be satisfied with a perfunctory yes or no; we must go into details, and by careful questioning we will often learn that a death which has been ascribed to influenza, menopause, confinement, pneumonia, bronchitis, typhoid fever, was preceded by many months of illness, was accompanied by loss of weight, night sweats or hemorrhage, was in fact an unrecognized, or by a curious paradox on the part of our patient, purposely concealed tuberculosis." The hunt for a source of infection should not stop with inquiries about the immediate family but should be carried further and the patient questioned carefully about his associates, both social and business, about the workshop and about his dwelling.

In Group A there was a history of cough in nineteen cases of the twenty-five in which the symptom was recorded. In six of these cases the cough had continued for three months and less than six, in two cases for six months and less than a year and in five cases for a year or longer. In Group B there was a history of cough in sixteen cases of the twenty-one in which the symptom was recorded. In two of these the cough had lasted for six months and less than a year and in nine cases the cough had lasted for a year or more.

Cough is usually one of the earliest symptoms and persists throughout the course of the disease. However, it must not be forgotten that some cases have more or less advanced disease before any cough appears. A cough that lasts for two months or more and that cannot be explained by some general or local condition should always be looked upon with grave suspicion.

In Group A in twenty-six recorded cases there was hemoptysis in eleven (frank hemorrhage in five, blood-streaked sputum in six). In Group B in eighteen recorded cases there was hemoptysis in four (frank hemorrhage in one, blood-streaked sputum in three). The one case in which the frank hemorrhage occurred was the woman I have already spoken of as having died of whooping cough. Of the three cases of blood-streaked sputum, two occurred among the seven that died of other causes than tuberculosis, one being the case of mitral stenosis and regurgitation, and the other being the one with emphysema and chronic bronchitis. The other one remaining case of blood-streaked sputum occurred in a boy of eighteen who had naso-pharyngeal catarrh, and who told me, when I examined him, that he still at times spits up blood-streaked sputum which comes from his nose.

Hemoptysis is probably the most pathognomonic symptom we have of pulmonary tuberculosis. Austin Flint in 1875 said, "Hemoptysis, the hemorrhage limited to the bronchial mucous membrane, and not dependent on disease of the heart, or on an injury of the chest, is always presumptive evidence of existing pulmonary disease." A little further on he says, "Hemoptysis occurs in some cases where not only the symptoms of pulmonary disease are wanting, but the result of physical explorations of the chest is negative. In a certain proportion of these cases it is probable that the hemorrhage is connected with a small affection which is latent as regards both symptomatic phenomena and physical signs." Osler mentions a study of Franz Stricker's of nine hundred cases of hemoptysis occurring in the Prussian Army. He says, "Among the conclusions that Stricker draws, the following are the most important, namely, that soldiers attacked with hemoptysis without special cause are in at least eighty-six and eight-tenths per cent. tuberculous. In the cases in which the hemoptysis follows the special exercises, etc., of military service at least seventy-four and four-tenths per cent. are tuberculous. In the cases which come on during swimming or as a consequence of direct injury to the thorax, about one-half are not associated with tuberculosis." I believe a safe working basis is to regard all cases of hemoptysis as of a tuberculous origin until proved otherwise.

Pain in the chest was observed in twelve out of twenty-three cases in which the symptom was recorded among the cases in Group A. In Group B it was observed in thirteen out of twenty cases.

The presence or absence of dyspnea was recorded in twenty-four cases in Group A and was present in twelve. Of these twelve, one case complained of dyspnea at night and the other eleven after exertion. In Group B dyspnea was present in fourteen out of twenty cases in which the symptom was recorded. Marked dyspnea usually comes on late in the disease but patients often suffer from slight dyspnea after exertion when the disease is in its incipiency; at times it is what first calls attention to their condition of health.

Temporary hoarseness was present in Group A in nine out of twenty-three recorded cases and in Group B in eight out of twenty recorded cases. There was no case in either group which gave a history of prolonged hoarseness. As a rule prolonged hoarseness comes on late in the disease, but any case with a history of prolonged hoarseness or repeated attacks of temporary hoarseness should be examined and watched with the greatest care.

There were gastric disturbances in seven of the twenty-three cases of Group A in which the gastric condition was recorded. In Group B, eight cases out of twenty had gastric symptoms.

Chills were present only in three cases of the eighteen recorded cases in Group A and in two cases of Group B out of the four that had the symptoms recorded.

Seven out of twenty-four cases in Group A had a history of night sweats and eight out of twenty cases in Group B.

The weight was recorded in sixteen cases of Group A, thirteen of them showing a definite loss. In Group B, nine out of fifteen recorded cases showed a loss of weight.

Fever was present in nineteen of the twenty-six cases of Group A in which there was a record of the symptom; and in Group B, it was present in fifteen cases and absent in eight.

Four cases in Group A out of the twenty-three in which the fact was noted had a history of a previous pleurisy and the same number in Group B out of the twenty-two recorded cases had had pleurisy. A history of pleurisy is always more or less of a suspicious fact when we remember that from eighty to ninety per cent. of all pleurisies are due to the tubercle bacillus.

Several of the cases in the two groups had histories of having had pneumonia, typhoid fever or influenza. But a history of these diseases is not suggestive unless you get a history of repeated attacks of any one of them. Patients sometimes tell you that they have had two or more attacks of pneumonia, or that they have had an attack of influenza every winter for some years. These attacks were probably not pneumonia or influenza but acute exacerbations of their tuberculosis. Another most suspicious history is that of typhoid pneumonia, either one attack or more. What exactly is meant by typhoid pneumonia is open to argument. It may be a case of typhoid fever developing pneumonia, or it may be a pneumonia which has a protracted course and the patient is in a typhoid state, but by careful questioning it will often be found to have been an attack of acute tuberculosis from which the patient has recovered.

In closing let me add that I am not pleading for the diagnosis of tuberculosis to be made from the history alone. Only that when the physician gets a history, not of one of the foregoing symptoms but of a combination of two or three or more of them, that he leave no stone unturned until a definite diagnosis is made either of tuberculosis or of some other condition which will account for all the symptoms. If he is unable, after repeated examinations, to solve the problem, and the history is suspicious, he should allow his patient to have the benefit of the doubt and put him on treatment for tuberculosis, which treatment can be carried out at home without seriously inconveniencing his patient, and I am sure will be attended by results most gratifying to the patient as well as to the physician himself.

1815 Spruce Street.

CORONARY SCLEROSIS WITH SPECIAL REFERENCE TO GASTRIC SYMPTOMS.

By I. W. HELD, M.D.,

NEW YORK.

ADJUNCT ATTENDING PHYSICIAN, HAR MORIAH HOSPITAL; ATTENDING PHYSICIAN, HAR MORIAH HOSPITAL DISPENSARY.

In the sense used by Cohnheim[1] the coronary arteries are terminal vessels inasmuch as their branches do not anastomose with each other sufficiently to maintain perfect circulation. In experimental ligations of the branches of the coronary arteries in cats and dogs, carried out in Porter's laboratory, Walter Baumgarten[2] demonstrated the following facts: (1) Ligation of the ramus descendens caused infarction in the anterior wall of the left ventricle, anterior papillary muscle, left half of the interventricular septum. (2) Ligation of the ramus circumflex caused infarction of the apex, posterior papillary muscle, a portion of the right ventricle, posterior wall of the left atrium, posterior one-third of septum. (3) Ligation of the right coronary artery caused infarction of a part of the right ventricle and the posterior portion of the appendix atrii. The nerve supply of the coronary arteries was demonstrated by Maas, who showed that vasoconstriction is exerted by the vagus, and vasodilatation by the accelerator nerves. Scaramucci's experimental demonstration in 1689 that the coronary vessels are emptied during diastole of the heart, thereby nourishing the organ, was confirmed by Porter[3] and his pupils.

The clinical picture of coronary sclerosis was already known to the ancients. Seneca, who himself was a sufferer from its attacks, described the symptom complex under the designation of "precellæ similis." The pains would start under the sternum and radiate down both arms, and he felt like losing his senses. Morgagni even described the autopsy of a man whose symptoms before death were those of coronary sclerosis as follows: "The inner surface of the aorta was studded with numerous elevations and pustules, the latter extending to the coronary arteries, one of which was entirely occluded." Other cases have been described by Hoffmann, but none of the older authors considered coronary sclerosis as an independent disease. It was not until 1786 that Rougnon, a physician of Besançon, gave an excellent description of the disease which five months later was followed by the famous article of Heberden who designated the symptom complex as angina pectoris, calling particular attention to the importance of not confounding the same with dyspnea. Hunder, the great clinician, who was himself a victim of the disease, shortly afterward gave a very exact description of the affection. However, it was left for Jenner to show the full pathogenic significance of the association of angina pectoris with coronary sclerosis, whose views were supported by the greatest clinicians of those days, chief among whom were Parry and Kreysing, the latter advancing the explanation that the heart muscle, being poorly nourished owing to coronary sclerosis, was unable to perform the extra task thrown upon it, thus explaining the occurrence of attacks on the slightest exertion.

Numerous other theories were promulgated to explain the symptoms of coronary sclerosis. One that deserves special mention is that by Reeder, an English author, who attributed them to ischemia of the heart muscle. Lussana, in 1858, advanced the theory that mechanical irritation of the cardiac plexus was responsible. Potain,[4] the famous clinician, in 1870, supported Reeder's view. Since then no epoch-making theories have been brought forth until of late the symptoms were attributed to lesions in the plexus of the nerves. This view has been supported by autopsy findings, as will be shown presently.

The pathological changes are almost invariably the following: The coronary arteries are irregularly dilated; their walls are thickened and their lumen is narrowed in many places; sometimes one

or the other of the coronary arteries is completely occluded. Microscopically sclerotic and connective tissue changes are found. The membrana elastica is found split in many places and sometimes completely occluded. The cells of the intima show fatty degeneration. The heart changes are variable, for which reason von Leyden[5] subdivides the same into four groups: (1) When the patient dies of an intercurrent disease, coronary sclerosis is only accidentally found, and the heart muscle shows neither macroscopical nor microscopical changes. (2) Myomalacia cordis (Ziegler), where one or the other of the coronary arteries is found completely obliterated, causing areas of softening and infarction in different portions of the heart muscle. (3) Myodegeneratio fibrosa, where the disease is of long standing; the heart muscle has undergone changes of repair, showing areas of fibrous tissue with white scars, mostly around the apex of the heart. (4) Mixed changes, where areas of infarcts are seen in some places, while in others there are changes of connective tissue formation. Efforts were made to find lesions in and about the cardiac plexus with a view to substantiating the above-mentioned nerve theory, and in this connection Lancereaux'[6] findings are worthy of mention. He describes the case of a man, 45 years of age, who suddenly died of angiosclerosis, in whom not only the usual findings were present, but also exudates in the fibers of the cardiac plexus. Similar observations were published by Heine, Haddon, Peter, Bareté and others.

Symptoms.—The most frequent clinical picture of coronary sclerosis is undoubtedly that of angina pectoris, characterized by the following symptoms: Sudden oppression behind the sternum, as if, as Hunter expresses it, the sternum were drawn to the spine; a feeling of strangulation with fear of impending death; severe pain in the sternum, sometimes in its lower and sometimes in its upper part. The pain is so severe that, should the patient be attacked while walking, he is afraid to move on. The pain usually radiates from the left shoulder down the arm and fingers, which feel numb. Sometimes it radiates down the right arm, or both arms, and fingers. The face is pale and usually covered with cold perspiration. There is often a flow of saliva, and the attack is often preceded by polyuria. The pulse is usually of high tension, irregular and slow; in fact, the severest types of bradycardia have been observed during a paroxysm of angina pectoris. At times, however, the pulse is quick and regular; at other times it shows no changes at all. With a favorable termination the patient usually belches gas, and feels collapsed for hours. Very often the first attack ends fatally. Arthur Douglas Hirschfeld[7] holds coronary sclerosis sometimes responsible for paroxysmal tachycardia; precordial pain, and sudden death without any previous symptoms, probably due to the presence of sclerosis for some time past, and to sudden arrest of the function of the heart muscle, causing death from thrombosis of the sclerosed artery. Often, however, *gastric disturbances* are the only complaint during life, while the real cause is sclerosis of the coronary arteries. The literature contains cases cited by von Leyden,[5] Pauli, and Kaufmann,[8] Dickinson, Broadbent,[9] Cabot, and others, where the symptoms were of a purely gastric nature, while the autopsy revealed coronary sclerosis as the cause of death.

Furthermore, there is a certain set of abdominal symptoms which are designated angina abdominalis, and are referable to arteriosclerosis. Usually these symptoms are as follows: The majority of the patients are males, well above 40. There is more or less continuous pressure in the epigastrium, particularly after meals. There is often a boring sensation, radiating up under the sternum, which, however, is not dependent upon meals, but rather due to psychic disturbance, or exertion. There is also a marked sensation of fullness after meals with slight dyspnea, and inability to lie down after meals owing to palpitation of the heart. Frequently there is nausea, but no vomiting. Severe paroxysms of pain with a sensation of impending death are not infrequent, and a number of cases of sudden death have occurred in this condition. The writer recollects two such cases where sudden death occurred with all the signs of epigastric pains, while the underlying cause was arteriosclerosis. The bowels are usually irregular; constipation is the rule.

A careful examination of the cardiovascular system will show that the blood pressure is usually high, 200 and higher; apex beat in the mammillary line to the left of the sternum; first sound muffled; or there may be a slight systolic murmur; the second aortic sound is strongly accentuated; face is usually pale. These symptoms should lead to the suspicion of central sclerosis, which is often justified, and well rewarded by corresponding treatment along this line. It is needless to say that the gastrointestinal tract should be thoroughly examined, as affections in this region may be associated with coronary sclerosis. It is only recently that Heinrich Citron[10] reported a case where autopsy disclosed the presence of duodenal ulcer associated with coronary sclerosis.

I may mention two cases from my own observation in which coronary sclerosis occurred with pronounced gastric symptoms.

Case I.—A.F., 53, barber. Previous history negative. Was perfectly well up to two years ago, when there was a sudden sensation of discomfort in the epigastric region. At first this occurred only after heavy meals, but later there were boring pains after light meals or no meals at all, also, and particularly so, after exertion. Appetite variable, bowels usually constipated. Patient also had severe attacks of gastric pains. A very careful examination of the gastrointestinal tract revealed nothing abnormal. Not so the vascular system: blood pressure 210 maximum, 190 minimum; apex beat weak, best palpable in the fifth interspace to the left of the mammillary line; on auscultation there was a very weak first and accentuated second aortic sound. This led me to suspect that the gastric symptoms were due to coronary sclerosis, and treatment was instituted accordingly with satisfactory results.

Case II.—L.G., 49, bookkeeper. Complained of symptoms similar to those in the first case. There were no objective findings in the gastrointestinal examination, while the blood pressure was 170 maximum and 145 minimum; there was a slight systolic murmur at the apex, not transmitted, with an accentuation of a second aortic sound, associated with a slight systolic murmur at the aorta. Taking these facts as well as the early age for sclerosis into consideration, I was led to suspect syphilitic infection, but the Wassermann test proved negative. I therefore instituted on general principles the treatment for coronary sclerosis, resulting in decided improvement.

Following are the reports of three other cases with autopsies which I had occasion to witness in Berlin last winter:

Case III.—J.B., 44, laborer, admitted to the Friedrichhain Hospital, Berlin, department of Professor Kroenig. There had been gastric disturbances for several months, high blood pressure, a second accentuated aortic sound with first muffled sound in the apex. After patient had been in the hospital for eight days he had a sudden attack of pain in the epigastric region, during which he spastically clutched his hands over the abdomen and expired. Autopsy by Professor Pick: Endarteritis deformans, coronary arteries markedly sclerosed. Arch of the aorta showed atheromatous changes, the heart muscle degenerative changes. Gastrointestinal tract as well as biliary passages perfectly normal.

Case IV.—N.R., 52, laborer. Gastric symptoms as in last case. Apex of the heart in the fifth interspace palpable in the left mammillary line; slight systolic murmur; blood pressure 190 maximum, 165 minimum. On the fifth day of his stay in the hospital there occurred a severe attack of gastric pain with fatal termination. Autopsy by Professor Pick: Left coronary artery completely occluded. Fibrous tissue of papillary muscle increased; aortic valves covered with calcareous deposits; absolutely no changes in gastrointestinal tract or biliary passages.

Case V.—Woman, 52, admitted to the Kaiserin Augusta Hospital, service of Professor Ewald. No complaints except of gastric origin. Hyperacidity. The cardiovascular findings during life were not very characteristic of coronary sclerosis, and the blood pressure was only 150. There was a slight increase or broadening of the aorta. After two weeks' stay in the hospital she succumbed to an attack of severe epigastric pain. Autopsy by Professor Oesterreich: Atheromatous deposits in the aorta. Erosions of the aorta extend to the coronary arteries, one of which was completely occluded. Gastrointestinal canal and biliary passages absolutely normal.

To explain the gastric symptoms in the presence of coronary sclerosis, various theories have been advanced. Kaufmann and Pauli[8] explain the same as follows: The disease of the inner layer of the blood vessels causes vascular colic ("Gefässkoliken," Nothnagel),[11] originating in the affected vessel and radiating to the abdomen. Buch[12] explains the symptoms as hyperesthesia of the sympathetic plexus. Other authors consider the abdominal pains to be due to ischemia of the gastric mucosa, analogous to dysbasia angiosclerotica (Erb)[13] of the lower extremities. This explanation would justify the designation of angina abdominalis.

Treatment.—The object of the treatment is twofold: (1) to prevent recurrent attacks during the intervals and (2) to combat the attacks, when present. To meet the first indication, the treatment should be directed to the etiology of the disease, and considering that syphilis, gout, diabetes, excessive indulgence in alcohol and meat diet (Bishop) and mental overwork are often instrumental in causing this affection, the first step should be to remove the underlying cause. As a prophylactic measure, it is necessary to forbid excessive exercise, overloading the stomach, walking against the wind, psychic emotion, and so on. The food should be easily digestible and nonfermentative; small quantities at frequent intervals are in order. It is advisable to put the patient for a short time on an exclusive lactovegetable diet; later, when meat is allowed, it should not be given more than once a day, and plainly prepared. Special care should be taken to restrict proteid food. Any indication of indicanuria should be closely watched, as Bishop[14] has shown that prevention of the same will markedly benefit the sclerotic condition of the coronary arteries. Should indicanuria persist, or should there be a tendency to gastrointestinal fermentation, tablets containing lactic acid bacilli, kefir, or buttermilk should be included in the diet. Alcohol and tobacco should be avoided. If the myocardium shows gross changes which are readily recognized, or minor ones as disclosed by the functional tests devised by Herz,[15] and Hoffmann,[16] or in the presence of kidney insufficiency and slight tendency to edema of the lower extremities during the day, to disappear at night, the salt tolerance of the patient should be determined by the procedure so ably worked out by Professor H. Straus.[17] In the presence of salt intolerance, salt in the diet should be restricted or entirely excluded for some time. If the patient is able to afford it, he should stay in a warm climate during the winter; otherwise he should remain indoors in inclement weather.

As to hydrotherapeutic measures, the patient should be cautioned against extreme temperatures of the water, and against staying in the bath too long. The temperature should range between 98° and 102°, and the time between 15 and 20 minutes. The bath should be followed by light massage. Hasenbroek[18] and also Oertel advocate massage of the heart, while A. Fraenkel[19] wishes to limit the same to very mild cases. As to carbonic acid baths, great caution should be exercised. They should only be given under competent supervision with strict observation of the temperature, which should begin at about 90° and gradually lowered to 80°. The bath should not last longer than 10 minutes at first; later it may be increased to 15 or 20 minutes, three times weekly, followed by light Schott exercises and rest for at least two hours. The blood pressure before the bath should be neither too high nor too low, and the effect of the bath must be such as to lower the blood pressure. Nor should the bath be taken immediately after meals; 1 hour after light meals or 3 hours after heavy meals should be allowed to elapse. Electric baths, in the form of 4-cell battery with hand and feet in water have been used. The high frequency current has of late been used by Laqueur[20] in the Virchow Hospital, Berlin, and he claims that they are effective in reducing the blood pressure and thereby relieving the symptoms. The method deserves a trial, coming as it does from such a reliable observer.

As to drugs, diuretin and iodides have proved the most useful. The former is given in 10-grain doses three times daily for two months; the latter, in the form of sodium iodide preferably, in 10- to 15-grain doses three times a day for six to eight weeks. In cases which do not tolerate sodium iodide, one of the newer compounds of iodine may be tried. Where blood pressure persists high, some of the nitrites, especially sodium nitrite, have been advised by Egbert Le Fevre as being a valuable drug in this condition.

To relieve the attacks, a hypodermic injection of morphine is often indispensable, and although its use has been disputed for a long time, the general opinion now is that its use is indicated and that there is no danger in administering it. Another drug that gives good results is amyl nitrite in pearls which are crushed and held in a handkerchief against the patient's nose for inhalation. One or two pearls, con-

taining three minims each, may be used. The vasodilatation it produces is shown by the flush in the patient's face and by its immediate relief. Counter-irritation to the chest and hot mustard footbaths are often beneficial. Carl Pototzky[21] has inaugurated partial carbonic acid baths ("Hafussi baths"—hand and foot baths) which are given by immersing the hands and feet in hot water impregnated with carbonic acid. These baths have afforded great relief.

THE MEDICAL SUPERVISION OF SCHOOL CHILDREN IN SOUTH MANCHESTER, CONN.

By THOMAS G. SLOAN, M.D.,

South Manchester, Conn.

Special Examination for Physical Defects.—In the fall of 1906, 72 children out of over 1600 were found to be a year or more behind their grade. Twenty-one of these were either non-English speaking or had been irregular in their school attendance, leaving 51 whose backwardness could not be explained. These 51 were examined for eye defects, hearing, and diseases of the nose and throat with the following results:

Eyes: Defective vision, 15 or 29 per cent.; blepharitis marginalis, 5 or 9 per cent.; conjunctival catarrh, 4 or 8 per cent. Nose: Mucopurulent catarrh, 2 or 4 per cent.; inferior turbinate enlarged, 8 or 16 per cent.; spur, 4 or 8 per cent. Tonsils: Enlarged or inflamed, 16 or 31 per cent. Adenoids: Needing operation, 16 or 31 per cent.; small, 13 or 25 per cent.; very small, 3 or 6 per cent. Ears: Defective hearing, 4 or 8 per cent.

Many children had more than one defect. Fifty of the 51 backward children, or 98 per cent., had one or more defects.

At the same time 257 children who were doing average work but who were suspected of having physical defects were examined with the following results:

Eyes: Blepharitis marginalis, 36 or 11 per cent.; conjunctival catarrh, 14 or 4½ per cent. Nose: Mucopurulent catarrh, 20 or 6½ per cent.; inferior turbinate enlarged, 38 or 12 per cent.; spur, 22 or 7 per cent.; septum displaced, 3 or 1 per cent. Tonsils: Enlarged or inflamed, 16 or 31 per cent. Adenoids: Needing operation, 120 or 39 per cent.; small, 84 or 27 per cent.; very small, 20 or 6½ per cent.

Two hundred and sixty-six, or 86 per cent., had one or more defects. One hundred and fifty-seven notices were sent to the parents of those children who urgently needed operation, and as a result 19 were operated on for adenoids or tonsils. This result may not seem very great, but a start was made and the education of the parents was begun, and as the resulting benefit to the children became apparent, we had less trouble in getting consent to operations.

In the winter of 1907 an examination was made of 266 children who were thought to be suffering from nose or throat troubles. This year we had 26 operations. The same year 1,437 pupils were examined for eye defects and 91 or 6 per cent. were found to be in need of treatment and as a result 20 were fitted to glasses.

In 1908, 204 children were examined for nose and throat troubles. One hundred and twenty-six or 61 per cent. needed operations or treatment. This year we got 13 operations and some were treated otherwise than by operation.

In January, 1910, a special examination was made of 1,564 pupils, all who were in attendance at that time. Our idea was more that of a coarse drag net to record the more serious defects than to have a list of less important defects as we were after practical results. In this examination the teeth were not noted unless bad enough to need extraction. Below is the result of the examination:

Number of pupils examined	1564
Defective teeth (needing extraction)	295
Enlarged tonsils	113
Adenoids	73
Adenoids and teeth	71
Tonsils and adenoids	62
Tonsils and teeth	44
Adenoids, tonsils and teeth	39
Teeth and markedly enlarged cervical glands	15
Enlarged cervical glands	4
Miscellaneous	16
Total	732

The adenoid cases per grade were as follows:

	Number Examined	Number Found	Per Cent.
High School	165	9	5
Grade VIII	89	6	7
" VII	168	19	11
" VI	182	27	15
" V	273	16	6
" IV	106	25	24
" III	105	46	44
" II	143	46	32
" I	242	48	20
Kindergarten	91	8	9
	1564	250	16

Comparison of 1,564 South Manchester school children with 323,344 New York City children, as follows:

	South Manchester	New York City
Percentage of children defective	46	75
Teeth	29	57
Adenoids	16	22
Eyes	7	11
Ears	2	1
Tonsils	14	
Pediculosis	4	45

In September and October, 1910, another examination was made of all school children in attendance, our feeling being that an examination made in the middle of winter when colds were prevalent would give too high a percentage of enlarged tonsils and adenoids on account of temporary inflammation from colds; in fact, this was found to be true in a few cases that came to our notice. For example: A boy was found to have tonsils that were very large and operation was advised. The day he was to go to the hospital he was again examined as they all are and his tonsils were practically normal. The explanation was simple. He was just getting over an attack of acute tonsillitis at the time of his first examination.

	January	October
Number examined	1564	1725
Defective teeth	30 per cent.	31 per cent.
Tonsils	14 per cent.	16 per cent.
Adenoids	16 per cent.	2 per cent.

The percentage of teeth and tonsils remain about the same. The difference in adenoids is due to the time of year, the number of cases that had been operated on, and because at this examination only the more severe cases were noted.

In October, 1911, 1,739 children were examined and defects found as follows:

		Per cent.
Teeth (including those needing extraction and those needing filling)	707	40
Tonsils, needing operation	83	5
Moderately enlarged	123	7
Adenoids (marked)	37	2
Cervical glands	23	1

The results of our work show particularly in the small number of adenoids found in the last two examinations, both in the early fall before colds are prevalent, to be sure, but the 131 pupils or 8 per cent. of the total number of children now in the school who have had either tonsils or adenoids or both removed, bring down the percentage very materially. More than this the parents have been educated in this direction. They see the advantage to the children and we do not have to urge them to permit the operation. Now they ask to have it done and a considerable number of operations have been done on children under the school age due to the results observed in our cases.

The most surprising observation to the examiner was the tremendous disregard shown to the care of children's teeth even among the better class of people. With only two or three exceptions children who brushed their teeth daily had good teeth, and the reverse was also true, and some enlargement of the cervical glands was the rule with bad teeth.

The expense of the operation for adenoids and tonsils as done at the Hartford Hospital is $3.50. In those few cases where even this amount could not be raised, we have found a way to procure it so that in every case when the parents are willing the operation has been done.

Medical Supervision as Carried on Throughout the Year.—The medical inspector is in his office at the school with the school nurse in attendance at 10 A. M. two mornings a week. To him are sent all pupils who the teachers think need attention, as those she thinks may have some contagious disease, sore throat, pediculosis, ringworm, impetigo, pink eye, injuries, etc. These children are either sent back to their rooms or sent home with a note to the parents. If advisable, throat cultures are taken and the children are not permitted to return to school until the culture is negative. No child who is sent home is permitted to attend school until seen by the medical examiner.

In case a child is sent home with an infectious disease, the other children in the family attending school are sent home and not allowed to attend school until two weeks after the house has been fumigated, and in cases of diphtheria until a negative culture is obtained, and in all cases after an examination by the medical inspector.

In cases of contagious disease reported to the Health Officer, all members of the family are excluded from school and are allowed back under the same conditions.

Pediculosis cases the parents are obliged to treat at home, and in case of necessity the nurse goes to the home and shows the mother how to treat the head.

Ringworm, impetigo, and pink eye are called to the attention of the parents with the advice to call on the family physician. When nothing is done the nurse treats the case under supervision of the medical inspector. She also cares for minor injuries and such emergencies as may occur.

Below is a table showing the cases of pediculosis seen by the medical inspector in the last six years:

	Number Examinations Made	Number Pupils Examined	Number Cases Pediculosis	Number Excluded
1905	1103	421	216	150
1906	1585	458	282	135
1907	2435	477	227	125
1908	1427	342	96	108
1909	1238	318	72	89
1910	1263	117	66	55

About six families are left who have to be watched for pediculosis.

The school population has increased very decidedly in the last six years and yet the number of children examined has been reduced from 421 to 117, the cases of pediculosis from 216 to 66, and the children excluded from school from 150 to 55. The results speak for themselves.

Number visits to school		77
Number examinations		1,238
Number children examined		218
Number children excluded		99
Pediculosis	72	
Sore throat	53	
Sore eyes	25	
Ringworm	14	
Tonsillitis	12	
Skin disease	10	
Cuts	7	
Poison	7	
Sores on face	7	
Boils	4	
Ear abscess	3	
Tuberculosis	2	
Mumps	2	

Chicago's 1910 Report

Number examined		820,655
Number excluded		14,653
Diphtheria	708	
Measles	1004	
German measles	397	
Scarlet fever	579	
Chicken pox	1010	
Mumps	1128	
Wooping cough	298	

I give above a detailed report of the medical in-

spector's work for 1909, taking that as an average year rather than 1910. when we had two epidemics, one of scarlet fever and one of diphtheria.

Medical Supervision During Epidemics. — In 1910-11 South Manchester was visited by a long lasting epidemic of scarlet fever and diphtheria which started before the schools opened in the fall and continued for several months. Ordinary precautions did not control it. It was finally controlled in the following manner:

Each morning the Health Officer reported the new cases and the children from those homes were at once excluded from school and not allowed to return until two weeks after the house was fumigated and in cases of diphtheria not until a negative culture was obtained and also after a careful physical examination. The specimens were sent to the Laboratory of the State Board of Health in Middletown. During the epidemic 389 cultures were sent to the laboratory 87 of which were positive.

In addition, the 481 high school and upper grade pupils in the high school building had their throats examined once. One culture was taken which was negative.

The pupils in the grammar school building averaging 850 were examined on six consecutive weeks. Two hundred and ninety-six cultures were taken, 56 of which were positive. A number of well marked cases of scarlet fever and diphtheria were found in the school. There were during the school year 65 cases of diphtheria and 75 cases of scarlet fever and 144 children in those families were excluded from school.

In figuring the cost of the epidemic the superintendent of schools presents the following figures:

Time lost by children who were ill	3696 days
Time lost by children who were excluded	4394 days
Total	8090 days

This represents 44 school years for one pupil or one year for 44 pupils. It costs $35.28 to promote one pupil one grade making a cost to the school district of $1,552. In addition many children were kept home from school by fearful parents and many were kept out while waiting for a report on their cultures, making a total cost through time lost by pupils of about $2,500. To this must be added the cost of medical inspection, fumigation, etc., and also the cost to the families of medical attendance, nursing, medicine, and time lost from work, making the total cost to all concerned about $15,000 for the epidemic.

If we had begun systematic inspection of all children in school earlier, the result would probably have been better, but our schools were not closed and the majority of the pupils received their regular instruction.

Circumstances outside the school and beyond control of the school authorities had more or less to do with the spread of the epidemic. Children who were excluded from school went to Sunday school, church, public lectures, and mixed on the street and in stores with other children and doubtless spread contagion. We feel sure that the school is the safest place for children under such circumstances as there they were free from contact with the slightly sick, but contagious, and from members of families where disease was present.

The Open Air School.—An Open Air School was inaugurated January 25, 1911. The necessary money was raised by the Educational Club. The School District pays the teacher and supplies the desks and regular school equipment. The tent in which the school sessions are held, the house where the children eat and rest, which is on the grounds with the tent, the necessary extra clothing, food and service are provided by the Educational Club.

The school opens at 8:30 when each child receives a cup of cocoa. A school session is held until 11:30 broken by recess and gymnastics. Recreation from 11:30 to 12:00 when a substantial dinner is served followed by a rest period of one hour. Then comes the afternoon session from 1:30 to 3:30 broken by recess and recreation.

The school accommodates twenty pupils. A list of candidates for the school is made by the various teachers and examined by the physician in charge who recommends those who are proper cases for the school. The pupils are discharged from time to time as they improve. They are examined several times a year by the physician and frequent records of weight, general and special conditions are kept. The children are anemic, heart cases, cases of enlarged tonsils and adenoids, or more properly those having the lymphatic diathesis, chorea, and malnutrition. We have had no case of tuberculosis although one cured case was entered and did very well, gaining 15 pounds.

All school work has been done under the tent. The temperature has varied from 16° to 102° and the teacher reports that the best work was done in the coldest weather. Owing to the varied ages the instruction has been of necessity individual to a great extent.

The physical gain has been general. Out of 30 cases 25 have gained in weight and almost all have improved in general appearance and appetite, nervousness, and ability to study. A special point has been made in teaching hygiene. Several have been discharged so well that they did not need the school any longer.

The Nurse.—The nurse is a very important part of the system. Her duties in general are as follows: (1) She helps select the pupils who ought to see the medical inspector. (2) She assists the medical inspector, the physician making the special examinations, and the physician in charge of the open air school. (3) She follows up such cases as may be necessary, advising parents as to proper medical attention and corrective measures. (4) She treats minor ailments under direction of the medical inspector, as ringworm, impetigo, etc., thus it is not always necessary to exclude such cases from school. (5) She takes evening temperatures in suspected cases of tuberculosis. (6) She visits pupils' homes and arranges with the parents for pupils to go to the hospital for operations for adenoids and tonsils and goes to the hospital with the children. (7) She takes the girls to the orthopedic clinic Saturdays. (8) She has charge of the girls' bathroom. (9) She takes care of emergency cases occurring in school.

Eye Examinations.—The State requires an examination of every child's eyes once in three years. This is done, and in addition the eyes of new pupils are examined every fall, and also those eyes that were found defective at the last examination are re-examined and notices again sent to the parents.

Baths.—Several years ago a room was fitted up as a bath-room. Thirty-two slate stalls were put in each having a spray on a universal joint so arranged that girls can use it without wetting their hair. A janitor has charge of the boys in the morn-

ing and the nurse looks after the girls in the afternoon. The general public is allowed to use the room evenings. Soap and towels are furnished. In the last school year boys took 8,861 baths and girls 2,773. During the 4½ years the bathroom has been in use 59,000 baths have been taken.

Miscellaneous.—Ordinary sanitary measures are taken, as a jet of water instead of drinking cups, paper towels, frequent fire drills. The school gymnasium is used to its full capacity.

As the State compels parents to send their children to school 200 days a year, it is the duty of the State to safeguard their health in every possible way, and our results in South Manchester justify the outlay.

The medical inspector receives $2 a visit or $2 per hour in making special examinations, the nurse $17 per week. The special yearly examination costs $50. The special equipment of the open air school and the extra first year's expense was about $1,500 and was paid by the Educational Club. During severe epidemics the cost is much greater, of course, on account of the extra work done by the medical inspector. The clerical work is done by the superintendent's stenographer and very complete records and statistics are kept, each child having a card with full information running from year to year.

The results given in different places in this paper fully justify the work and expense, but the gain to the children in health, strength and ability to better provide for themselves is far more than any financial consideration.

ORGYIA LEUCOSTIGMA.

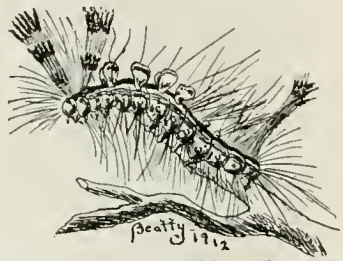
A FACTOR IN THE CAUSATION OF OPHTHALMIA NODOSA.

By GEORGE WESLEY BEATTY, M.D.,

BROOKLYN, N. Y.

From May until late in September and sometimes October, the shade trees in our city streets are covered with a peculiar caterpillar—the larva of the white-marked tussock moth or *Orgyia leucostigma* (Smith & Abbot).

The tussock moth is a native of North America and ranges from Florida north along the eastern coast to Nova Scotia and westward as far as Nebraska (at the present writing). Its food consists of almost all varieties of shade, fruit, and ornamental trees; the conifers, however, are singularly immune to their attacks.



The caterpillar of the Tussock Moth, *Orgyia Leucostigma.*

Here in New York City they seem to have a predilection for maples, horse-chestnut, elm, and catalpa trees and rose bushes.

A little knowledge of the life history and habits of this insect will not be amiss. The eggs are deposited late in September, and, winter over, on tree trunks and the larger branches, under fences, copings, and in fact wherever a crevice affords a shelter. They are detected at a glance by the frothy, glistening appearance of the white sac which contains the eggs. This sac is attached to the cocoon. It is pure white and appears like a mass of cotton that has been "sized" with shellac and glistens. Along some time in May, in this locality, the caterpillars hatch; they molt five times, *i.e.* they cast their skin, exhibiting different characteristics after each molt.

The young drop down on silken threads if the trees are jarred, and often without this provocation. They are blown by the wind and in that manner spread to other trees at great distances. When full grown or nearly full grown, they are untiring travelers, crawling down from the home tree where they were hatched, and crossing large areas of ground to attack a new tree. In this way they go from tree to tree, making extensive migrations. Often the caterpillars drop from the trees on the passer-by, and crawling along the edge of the collar small body-hairs embed themselves in the skin, giving rise to more or less irritation.

It is customary to spray the trees with solutions of arsenic; this poisons the leaves and in this way when the caterpillar eats them, millions are destroyed. Later in the season the walks are filled with débris of leaves and dead caterpillars; this is hurled along by the wind, automobiles, cars, etc., and the hairs are embedded in the conjunctivæ of pedestrians and others, giving rise to an annoying ophthalmia.

Usually the patient applies for treatment shortly after the introduction of the hairs into the eyes, for relief from the severe irritation which he is creating or aggravating by constant rubbing.

Two of my patients in stating the cause of the irritation, said they had brushed one of these red-headed caterpillars from their faces and had gotten some of his hair into their eyes, which began to itch and burn almost immediately. I relieved my cases by brushing the conjunctivæ gently with absorbent cotton backward and forward, with the hope of entangling the spiny hairs in it and thus removing them. I then washed the eyes, using an eye-cup. This afforded considerable relief and the patients were sent away with a bland collyrium to be used thrice daily in each eye. little less than a month later one of them returned with a nodular condition of the cornea resembling tubercles. The nodules were not many, but I referred him to an oculist, who, after giving due consideration to the history of the introduction of the hair from the caterpillar, treated him for a secondary keratitis with heat and atropine. He made an uneventful recovery.

I have had other cases in which a nodular condition of the conjunctivæ was produced by the introduction of caterpillar hairs, but I feel that these two will suffice to make my point.

I have had other cases apply for treatment of the erythema occasioned by these hairs becoming embedded in the skin of the neck where the caterpillar had been walking along the clothing. In every instance I brush the skin briskly backward and forward with absorbent cotton to remove the hairs, much the same as we remove the microscopic spines of the cactus pear and cowhage from the skin. I then apply some soothing agent and protect the neck from the clothing, and recovery quickly follows. In one instance the irritation was so great and the consequent scratching so severe that a true traumatic dermatitis was developed.

PHOSPHOPROTEINS IN DIET.

By FELIX VON OEFELE, M.D.,

NEW YORK.

We are indebted to Liebig for the division of organic substances into carbohydrates, fats, and proteins. For a long time we have known that this division is insufficient and of proteins especially that there are many different kinds which have been divided into numerous groups. In therapeutics, however, the differentiation of protein is either not observed at all or is carried to extremes. I must emphasize that in therapeutics the term proteins should no longer be indiscriminately used as a unity. On the other hand, the classification of proteins should be as simple as possible.

Briefly I will refer to a passage in O. Hammarsten's "Textbook of Physiological Chemistry." "The several protein substances contain carbon, hydrogen, nitrogen, and oxygen; the majority contains also sulphur, a few phosphorus, and a few also iron." If we disregard iron this chemical division gives us a simple and practical classification, and we get two groups of proteins: one rich in sulphur, the other rich in phosphorus. In a few instances we find that a protein substance is rich or poor in both elements. Most proteins, which are of interest in therapeutics, contain sulphur and phosphorus, but as already mentioned, one element usually predominates over the other. In the living organism both groups are always sharply separated. In the cell those rich in sulphur are found in the plasma and the phosphorus-rich proteins in the nucleus. In the process of digestion the former are chiefly digested by pepsin and muriatic acid and the latter by trypsin in alkaline solution. The cells of the epidermis, epithelium, and endothelium chiefly contain plasma, and therefore much sulphur and little phosphorus. The nerve structure contains hardly any plasma, but is derived chiefly from nucleus with, therefore, much phosphorus and very little sulphur.

These facts have much to do with my discovery of selenium as a remedial agent for cancer, but their importance extends beyond the limits of cancer research—they form a rational basis for studies in general dietetics. In the cell the seat of life is in the nucleus. Therefore, in practical dietetics we must not be content simply to prescribe any nitrogenous diet, but in one class of cases we should give proteins rich in sulphur and in another class those rich in phosphorus.

It is very important to know the indication for proteins containing phosphorus, for these affect the life of the cell nucleus, and, therefore, the whole economy of the body; but it is not always an easy task to supply what is needed as there are many proteins rich in sulphur, but only a few rich in phosphorus.

During seventeen years of private dietetic practice in German health resorts I had most gratifying results in employing either proteins rich in phosphorus or those rich in sulphur. There was one drawback to this, namely, it proved too expensive for the average patient, but that could not be helped, because there are as yet no satisfactory artificial foods fulfilling all requirements. In cases requiring proteins rich in sulphur I prescribed the white of eggs prepared in different ways and the yolk whenever phosphorus-rich proteins were indicated. Whenever the patients could afford to live on this diet I have always been satisfied with the results obtained. I am convinced that the whole egg is a fit food only for a healthy person, but not for a patient.

I will refrain from giving statistics, for to state a few cases only would be of no use. On the other hand, it would take too much time to classify all the cases I have had during these seventeen years. Suffice it to call attention to the above and to refer the reader to textbooks of physiological chemistry for further details.

326 East Fifty-eighth Street.

Treatment of Prolapsus Uteri.—M. Potocki believes that prolapsus uteri is almost always found in women who have been pregnant, and arises from the fact that they have passed through labor. Aside from the rupture of the perineum, which may occur at that time, there are various other mechanisms which assist in bringing about prolapsus after delivery. The parts are softened and distended during pregnancy, and the cervix may become much elongated. During gestation parturition and the puerperal state organic modifications occur which predispose to prolapsus, and lesions occur, some of which are curable while others require operation. Stretching and tearing of the cervix may occur through delivery before dilatation is complete; during labor the head drags upon the connections of the uterus with the bladder and rectum and tears them away from their natural supports. This may be prevented by the watchful obstetrician and the descending parts of the canal may be pushed upward with the hand between the pains and maintained there during the pain, when they will slip upward. Operative labors cause tearing of the ligaments and sphincters. A good preventive measure is dilatation of the vagina before operative accouchements by means of a rubber balloon. This renders extraction easy by putting an end to the resistance of the soft parts. After labor all tears should be repaired at once. The author believes that it is a mistake to allow the woman to get up sooner than three weeks after labor, since the weight of the uninvoluted uterus tends to cause prolapse. When there are no tears, but simple relaxation of muscles and ligaments, the author thinks that massage and electricity are valuable to restore the tone of the parts. The pessary is an instrument that not only is not dangerous, but that properly fitted is of the greatest value in moderate prolapse when operation is not desired by the patient. Hard rubber pessaries are most satisfactory, and the smallest that will do the work is most desirable.—*Annales de Gynécologie et E'Obstetrique.*

The X-Ray Treatment of Splenic Enlargement in Children.—G. A. Petrone and M. Lo Re report their results in eight cases. The results were poor in one case of Leishman anemia and one of anemia splenica pseudoleucemica. In one case of malaria with greatly enlarged spleen the *x*-ray treatment, together with the administration of quinine, was very effective, although hitherto quinine and arsenic alone had proved valueless. In four cases of anemia splenica pseudoleucemica the spleen was brought back quickly to its normal size. Another case was greatly improved, but died of bronchopneumonia.—*La Pediatria.*

Asthma with Swollen Middle Turbinals.—E. A. Peters reports the case of a woman, aged forty-two, whose illness began eighteen months ago with paroxysmal rhinorrhea; lately the patient has developed asthma, which is worse at night. The nose presents a condition of chronic rhinitis; the inferior turbinals are swollen. The middle turbinals are edematous and compress the septum. This last condition is characteristic of nasal asthma.—*Proceedings of the Royal Society of Medicine.*

RABIES IN THE UNITED STATES.

A RÉSUMÉ of the prevalence and distribution of rabies in the United States during the year 1911 is given by A. M. Stimson in the Public Health Reports for July 12, 1912. From this it appears that the most striking feature in the prevalence of this disease has been its spread to the Pacific Coast States which were apparently entirely free from it at the time of the former investigation conducted by the Public Health and Marine-Hospital Service in 1908. Thus, in California in 1908, there was not a single case of rabies reported, whereas in 1911 there were 124 persons who received treatment for this disease. More cases were noted in New York than any other single state. Here 889 persons received antirabic treatment and thirteen deaths occurred.

The whole investigation serves to indicate that all over the country the number of localities infected by rabies has increased. Although there has been a generalized spread to previously unaffected territory, it is probably true that the increased activity of health authorities and the greatly extended facilities for the administration of protective treatment have served to bring to light many cases of animal infection which formerly would have escaped notice. However, making due allowance for the more complete recording of all cases, Stimson still believes that there is an actual increase of rabies throughout the country at large. In marked contrast to the increase among the lower animals is the diminution in the number of human deaths. These amounted to only 12 per cent. of the total number of cases. A prominent factor in this decrease in the death rate is undoubtedly due to prompt resort to antirabic inoculations of exposed persons.

It has now become possible for the person who has been bitten by a supposedly rabid animal to avail himself of the immunity conferred by inoculation with comparative ease. In 1908 there were twenty-three institutions in this country where the Pasteur treatment could be administered. Now there are forty-two such institutions. Besides this there are five firms and laboratories that furnish materials for inoculations to practicing physicians. In 1911 the Hygienic Laboratory in Washington distributed virus for 942 cases. In the year 1911 more than twice as many took the treatment as in 1908, when the whole number who are known to have availed themselves of this method of combating the infection was only about 1,500. In 1911, on the other hand, there were 4,625 persons who received the Pasteur treatment. The total number of deaths from rabies in the whole United States so far as ascertained during 1911 was ninety-eight. Of these forty-four occurred in children between the ages of eleven and twenty. The period of incubation as ascertained in sixty-five cases varied from ten to twenty days in eleven instances, twenty-one to thirty days in nineteen, thirty-one to forty days in eight, and forty-one to sixty days in eight. There were ten cases in which the period of incubation was between two and four months, three from four to six months, and two from six to twelve months, whereas three were reported in which it extended over a year. The average incubation period in all cases excluding those over one year was 49.25 days. Of sixty-four cases thirteen received the infection in the month of August, but the other months were practically all equally represented.

From the foregoing data Stimson concludes that the decrease in the number of human deaths coincident with an increase in the number of antirabic treatment inoculations effectually disposes of the claims of the opponents of the Pasteur method that treatment causes rather than prevents rabies. He is of the opinion that the total death rate in persons taking the treatment was probably less than 0.8 per cent., and that even this small mortality can largely be accounted for either by delay in the treatment or because the incubation periods were too short to permit of immunization.

VISION IN RELATION TO MARKSMANSHIP.

AN English physician, Edridge Green, has been calling attention recently to the inadequate tests employed for men in the British navy. It goes without saying that for the performance of certain duties which fall to the lot of sailors, correct vision is absolutely necessary. In the *United States Naval Bulletin* issued in July, 1912, Surgeon E. J. Grow, U. S. N., deals with the question of vision in relation to marksmanship and brings out some very interesting points. Two hundred and seventy heavy-gun pointers and trainers of the U. S. navy were subjected to ocular examination. This included vision, refraction of each eye under a cycloplegic, the range of accommodation before, during, and after cycloplegia, effect of miotics, muscle tests at varying distances, and ophthalmoscopic examination in every case. In the paper, however, Grow considered only the results of vision, refraction, and ophthalmoscopic examinations.

The most important of the conclusions reached were as follows: Among the gun pointers of the U. S. Atlantic Fleet who were examined, a reduction of visual acuity was almost invariably commensurate with and due to the astigmatism present. Astigmatism of more than 0.75 diopter blurs and often doubles one of the cross lines in the telescopic sight and therefore interferes with accu-

rate aiming. Astigmatism of less amount may be considered as having a negligible effect, so far as pointing is concerned. A visual acuity of $\frac{20}{15}$ will, in a simple and practical way, eliminate all cases of astigmatism and myopia which by any chance would reduce or interfere with the most accurate aim which is possible to be obtained through telescopic sights. Plenty of men can be obtained who have the vision, and nothing is to be gained by a higher visual requirement. The elimination of dangerous amounts of hyperopia cannot be obtained by simple visual tests. When the condition is suspected a special ocular examination should be required to determine the amount. Hyperopia of over 3 diopters should be cause for rejection. Exceptional vision is no guarantee of good shooting and ordinary or slightly reduced vision, if associated with no more than 0.75 diopter of astigmatism, is of no hindrance when U. S. navy telescopic sights are used. Twenty-nine per cent. of the gun pointers and trainers examined failed to meet the visual requirements which have been in force since July 1, 1908. Many of these men have had several years' experience in heavy-gun practice and made most excellent scores. A slight diminution of vision often follows long continued practice with telescopic sights. Such men should be allowed a moderate reduction in visual acuity so that they will not be disqualified for an ocular defect when it is of such amount as to be of no determinable importance. Care should be taken that the individual who adjusts and fixes the telescopes in focus is free from any error of refraction which would preclude the possibility of others, who may be called upon in succession to use the same sight, from obtaining accurate aim. It is impracticable for gun pointers to wear glasses correcting their visual error and equally so for each individual to change the telescopic sight to suit himself. Consequently, it is imperative that the eyes of all who are to use these sights should be so nearly normal that the gun pointers can instantly use any telescope as they find it with a maximum of aiming efficiency. In reference to small arm shooting and rifle shooting, the relation of eyesight to markmanship is valueless when an ordinary service target is the object.

There is, stated Grow, an intensely practical side to this important subject of the relation of vision to markmanship which must be carefully considered. In view of all the evidence obtainable, it is believed that the best interests of the service will be furthered, as far as eyesight can possibly be concerned in relation to shooting with telescopic sights, by adopting the following requirements: (1) All candidates for the original rating of gun pointers should have a minimum visual acuity of $\frac{20}{15}$ in the sighting eye and $\frac{20}{20}$ in the other eye. (2) Hyperopia of over 3 diopters is cause for rejection. (3) The medical officer of each ship should carefully reexamine the eyes of all men holding these ratings at the beginning of each calendar year. If the vision has fallen materially since the last examination or evidence of asthenopia or disease exists, an ocular examination should be made by some one trained in ophthalmology. (4) Gun pointers and trainers who have served as such during one enlistment may on subsequent enlistments be accepted with a minimum visual acuity of $\frac{18}{20}$ in the sighting eye and $\frac{15}{20}$ in the other eye, provided such reduced vision is not due to progressive organic disease, myopia, or astigmatism of over 0.75 diopter. (5) In all cases vision should be tested by the so-called navy "unlearnable vision test card" as there is considerable temptation to learn the letters found on ordinary charts by those especially anxious to secure or retain the rating of gun pointer or trainer.

CERTAIN PHASES OF THE TUBERCULOSIS PROBLEM.

Probably no disease has ever been so freely discussed in the medical and lay press as tuberculosis. Sometimes one is led to think that so much is written concerning this most prevalent malady that the public may become somewhat weary of the subject. On further thought, however, it appears evident that it is good policy to keep the matter always in the limelight and to impress continually on the minds of the people the fact that pulmonary tuberculosis is not only worldwide but, what is of more importance, that it can be prevented and successfully treated. The fact that it is both preventable and under certain conditions curable should be made the text of every sermon dealing with the disease. In the *American Practitioner* for July, 1912, is a series of articles which forcibly bring home the truth of the statement. Adami in the first of these articles draws attention to the possible curability of tuberculosis, showing that in recent years some very remarkable results have been obtained in the treatment of infections produced by minute animal parasites, and he is optimistic enough to hope that the day may not be far distant when similar results may be obtained in the case of minute vegetable parasites.

C. A. Hodgette deals fully with the work and methods for the alleviation of tuberculosis, pointing out that the means of combating tuberculosis have increased largely of late. Incidentally he lays stress on the fact that the sanatorium is only one phase of the work against tuberculosis, and perhaps not such an important one as some of those interested therein endeavor to make out.

The supreme importance of early diagnosis of tuberculosis is dwelt upon by Robert C. Paterson who, after stating that practically every adult is or has been infected, expresses the opinion that if some of our energies were directed to keeping these infected persons from breaking down and developing pulmonary tuberculosis, by raising their powers of resistance, the results would be even more gratifying than at present.

Notification again is a *sine qua non* in the successful campaign against tuberculosis for, as

Edward Craig says, it converts the patient from a source of infection to a focus of prevention. The province of Ontario, or rather the government, has always been extremely generous with money the use of which is calculated to conserve public health, to aid education, and to advance the material prosperity of the province. This has been especially evident in the thorough manner in which it has coped and is coping with the problem of tuberculosis within the borders. J. W. C. McCullough deals in the same journal with the system of public health organization in force in Ontario.

As said before, it is by constantly ventilating the subject of tuberculosis in the medical and lay press that the profession and the public are induced to cooperate and join earnestly in the crusade against it. In such concerted efforts intelligently applied the only hope of its eradication lies.

BRASS MOLDERS' FEVER.

Fever was once believed to be a mysterious process representing the summation of Nature's resources for throwing off disease. After the discovery of the heat-regulating center it became evident that any agency which could influence the latter could raise or lower the temperature, but a distinction soon came about between fever proper and hyperthermia. The latter could occur under a great variety of circumstances; for example, in severe acute drug intoxications. It could be determined to a slight degree by purely physiological factors, such as exercise or hot baths. In hysterical subjects the temperature might attain a surprising height, yet be unaccompanied by collateral evidences of fever. The latter properly represents a syndrome in which elevation of temperature is but a single component, others being malaria, myalgia, rigors—in fact, acute toxemia.

A generation ago there was no common knowledge that any drug could cause a febrile syndrome or even hyperthermia without a general disturbance of the whole economy. Our older materia medicas recognized no class of pyretogenous substances. Perhaps the discovery of the tuberculin reaction was the first advance in this direction. Here a very minute dose of a complex organic substance was seen to be able—not, to be sure, in a normal subject—to cause a distinct febrile syndrome. At a later period we began to hear of salt fever and nuclein fever. Yet it would appear that the entire syndrome of fever has been duplicated for many centuries in the persons of brass molders. Not only fever, but the more tangible subjects of natural and acquired immunity to disease have been demonstrated for ages in connection with alloying tin and copper.

At a recent meeting of the Verein für wissenschaftliche Heilkunde in Königsberg (*Muenchener medizinische Wochenschrift,* June 18), Kisskalt discussed the subject of brass molders' fever and allied industrial diseases. The affection in question is due evidently to the inhalation of zinc vapor. This is accompanied by cough, but a period of latency follows. After several hours prodromes of clinical fever are apparent. There is a chill, followed by a rise of temperature to 40 degrees C. The pulse rises from 100 to 120. Before the advent of the chill there are malaise and backache. The fever is usually slept off. In the natural course of events three individuals out of four who engage in this work have this fever. The fourth has natural immunity. Of those who develop the disease, a certain number acquire immunity, while others evidently do not. But under industrial hygiene the affection has been largely diminished in frequency. That the febrile syndrome is due largely to zinc has been proved by animal experiment.

Convulsions in the Newborn.

An important distinction is pointed out by C. Stamm (*Archiv für Kinderheilkunde,* June 15, 1912) in contrasting the convulsions that occur shortly after birth with those that arise in later infancy and childhood. In the former case the convulsions are rarely of functional nature, while in the latter instance they are chiefly the manifestation of spasmophilia, a constitutional anomaly depending upon mechanical and electrical overexcitability of the entire nervous system. The rarity of this form of convulsions in early infancy is explained by the fact that at this period of life there is a diminution in the irritability of the peripheral nerves. The form of convulsion that ushers in an infectious disease is not to be expected in the newborn. In these there have been reported rare instances of reflex convulsions such as those resulting from a too hot or a too cold bath. The offspring of an eclamptic or nephritic patient may have convulsions, and instances of genuine epilepsy in the newborn have been observed. Convulsions may be one of the symptoms of septic disease or tetanus in the newborn. As a rule convulsions at this period of life point to some gross lesion of the brain as the immediate cause. This lesion may be a hemorrhage that has resulted during labor without necessarily any noticeable trauma or asphyxia having been present. In these cases there may occur several days after birth manifestations of increased intracranial pressure without a noticeable injury to the skull. Meningeal and intracranial hemorrhage may be caused by asphyxia or traumatism to the blood vessels. The usual site of hemorrhages is the subdural space in the region of the longitudinal sinus. Of diagnostic importance are the symptoms of increasing intracranial pressure, and the presence of blood admixed with the cerebrospinal fluid obtained by lumbar puncture. Sometimes the latter procedure is sufficient, in mild cases, to effect a cure. In cases in which there is a progressive increase in the intracranial pressure, the operation of decompression by trepanation is indicated. Next in frequency to the traumatic cerebral hemorrhages of the newborn are those of syphilitic or parasyphilitic origin. Other causes of convulsions at this period of life are syphilitic meningitis, encephalitis, and myelitis, purulent meningitis, embolic abscesses, encephalitis, and sinus thrombosis, and congenital anomalies and neoplasms, such as scleroses and porencephalus.

News of the Week.

Prizes in Therapeutics.—The American Therapeutic Society at the annual meeting held last June voted three prizes of $250, $150, and $100, respectively, to be awarded to the best reports on subjects relating to therapeutics, with the following conditions: The competition is limited to qualified physicians in the United States and Canada. The sub-

ject of the competition is limited to a substance or preparation which is official in the United States Pharmacopeia. The research may be either wholly laboratory or wholly clinical, or laboratory and clinical combined, and must be conducted in a public institution. The reports must be typewritten and submitted to the committee before April 1, 1913, and must be marked with a distinctive word or motto and accompanied by a sealed envelope similarly marked and containing the name and address of the competitor and of the laboratory or hospital where the research was conducted. Dr. Raymond Webb Wilcox of 679 Madison avenue, New York, is the chairman of the committee on the prize competition.

Suicides in New York.—Statistics compiled in Albany recently show that during the first six months of 1912 a total of 678 persons took their own lives in New York State. Of the various methods chosen the favorite was gas inhalation which caused the deaths of 160 persons. Hanging was used by 144; shooting by 141; poison by 130; the knife by 51; and drowning by 20. Thirty-two killed themselves by jumping from high places. The greatest number of suicides was in May, 132, and the smallest in January, 93.

Hospital Alterations.—Plans have been filed with the building department for alterations to be made at the Roosevelt Hospital, New York. They call for the fireproofing of the stairwell, the staircase, and the elevator shaft, for making four new rooms in the roof house, and for raising the ceiling of the operating room, all at a cost of about $15,000.

Plague Situation Under Control.—The reports from San Juan, Porto Rico, state that the situation there as regards bubonic plague is absolutely under control. No new cases are developing. The stories of destitution on the island are denied by the authorities, who state that there is no need for outside help and that in the various towns where it has been necessary to force the inmates of infected houses to vacate the premises public subscriptions have been raised to care for the sufferers and there has thus been no hardship as a result of these sanitary measures.

Miss Helen Keller Sings.—Miss Helen Keller, whose achievements in spite of her disadvantages have been many, exhibited to the Otological Congress in Boston, on August 16, her recently acquired ability to sing. She also addressed the congress in three languages—English, French, and German.

To Save Defectives.—The establishment of a laboratory of experimental psychology for the study of all inmates received in the Indiana State Reformatory at Jeffersonville was announced recently by Superintendent David C. Peyton. The plan includes a propaganda for converting reformatories into training schools for unfortunates whose deficiencies have betrayed them into crime. Mr. Peyton will be assisted in the experiment by Prof. R. B. von Kleinschmid who has for several years held the chair of education and psychology in Depauw University.

Quadruplets.—Boston, Mass., has added to its achievements, the possession of four children born at one birth, all alive and well. Quadruplets are rare, even in Boston, but these children have showed every intention of living.

Inspect Ship for Cholera.—The Fabre liner *Canada*, which arrived in New York from Marseilles on August 12, was detained at Quarantine because of three suspicious cases of illness which occurred during the voyage. Bacteriological examination of the steerage passengers was negative, however, and the ship was released on the following day. Reports have been received in New York of an outbreak of cholera in Russia within 250 miles of Libau, the chief seaport on the Baltic, and the Health Officer of the Port of New York announces that all ships coming from there will be subjected to a strict examination.

Good Week for Babies.—During the week ending August 11, there were in New York 358 deaths of babies under one year of age, a decrease of thirty-eight as compared to the previous week. The milk stations throughout the city had during the week an enrollment of 17,147 babies among whom there were only thirteen deaths, and the Babies' Welfare Association points with pride to the low records in infant mortality made this summer.

A Clinic for Gonorrheal Vaginitis.—The Mount Sinai Hospital Dispensary has inaugurated a special class for the treatment of these cases occurring in children and has appointed to the department a special physician, who is assisted by a graduate nurse. The cases enrolled since the inauguration of this class are so numerous that the dispensary has been compelled to restrict its treatment to children resident in its immediate neighborhood.

The Fifteenth International Congress on Hygiene and Demography will be held at Washington, D. C., September 23-28, 1912. The president of the United States will be the honorary president of this international congress. The president of the congress is Dr. Henry P. Walcott of Massachusetts, the secretary, Dr. John S. Fulton, Senate Annex, Washington, D. C. Thirty-two foreign countries have accepted the invitation of this Government to take part. All the States of the Union have also accepted the invitation to participate officially in the meeting. The responsibility for the conduct of the congress has been assumed by the Department of State.

The Jewish Maternity Hospital.— We are requested to state that the dormitory of this institution, in which a slight fire occurred last week, is not in the hospital itself, but in a separate building.

Direct Transfusion of Blood.— Dr. Soresi, 75 West Fifty-fifth street, New York, requests that surgeons who have performed direct transfusion of blood send him reports of their cases for use, with due credit, in a forthcoming work on the clinical value of transfusion.

Results of Opium Conference.—Twelve Latin-American countries have notified the United States of their intention to sign the international opium convention drawn up at The Hague last January, thus pledging themselves to join in the suppression of the opium traffic. The list includes Mexico, Guatemala, Panama, Ecuador, Honduras, Cuba, Costa Rica, Dominican Republic, Hayti, Salvador, Bolivia, and Chile. The United States in accordance with its agreement at The Hague is cooperating with the Netherlands in obtaining the signatures of the governments of Latin-America.

Gifts to Charities.—Mr. James B. Brady of New York has, it is reported, given the sum of $220,000 to the Johns Hopkins Hospital, Baltimore, for the establishment of a ward for the treatment of diseases of the kidney.

The Chicago Winfield Tuberculosis Sanatorium has received a gift of $25,000 from Mr. Julius Rosenwald of that city, who celebrated his fiftieth

birthday by large gifts to various educational and philanthropic institutions.

By the will of the late Miss Theresa Foy of New York, St. Vincent's Hospital in this city is to receive a share in the residue of the estate, amounting to about $3,000.

Dr. Arthur I. Kendall, instructor in preventive medicine and hygiene at the Harvard Medical School, Boston, has accepted an appointment as professor of bacteriology in the Northwestern University Medical College, Chicago. He will there direct the study of tuberculosis and its prevention under the fund recently given to the University by Mr. James A. Patten.

Dr. George William Beach, formerly assistant superintendent of the Iowa State Sanatorium for Tuberculosis, has been appointed superintendent of the Minnesota State Sanatorium for Consumptives, succeeding Dr. L. B. Ohlinger, resigned.

Passed Assistant Surgeon W. H. Frost of the United States Public Health and Marine Hospital Service, Washington, has been sent to Buffalo, N. Y., to assist in fighting the epidemic of infantile paralysis there. Request for Federal aid was made by the State authorities, who felt themselves unable to cope with the situation.

The American Electro-Therapeutic Association will hold its twenty-second annual convention at Richmond, Va., on September 3, 4, and 5, 1912, under the presidency of Dr. William D. McFee of Haverhill, Mass. Copies of the interesting programme which has been arranged may be obtained from the secretary, Dr. J. Willard Tavell of 27 East Eleventh street, New York.

Sumter County (Ga.) Medical Society.—At a meeting held in Americus, on August 8, this society was reorganized with the election of the following officers: *President,* Dr. Louis F. Grubbs, Americus; *Vice-President,* Dr. W. S. Prather, Americus; *Secretary-Treasurer,* Dr. T. Lewis.

Upper Peninsula Medical Society.—At the annual meeting held at Menominee, Mich., on August 8, the following officers were elected: *President,* Dr. Edward Sawbridge, Stephenson; *Vice-Presidents,* Dr. Henry S. Smith, Ishpeming; and Dr. C. Frithiof Larson, Crystal Falls; *Secretary,* Dr. A. W. Hornbogen, Marquette.

American Otological Society.—At the annual meeting held in Boston during the second week of August, the following officers were elected: *President,* Dr. Clarence John Blake, Boston; *Vice-President,* Dr. B. Alexander Randall, Philadelphia; *Secretary-Treasurer,* Dr. Henry O. Reik, Baltimore.

Pennsylvania State Bureau of Medical Education and Licensure.—At the recent State medical examination held at Harrisburg of 407 applicants for license to practise medicine in the State of Pennsylvania 284 qualified and 123 failed. The next meeting of the bureau will be held at Harrisburg December 3, 4, and 5.

Obituary Notes.—Dr. Thomas B. McClintic, Passed Assistant Surgeon, United States Public Health and Marine Hospital Service, a graduate of the University of Virginia, Department of Medicine, in 1896, a member of the American Medical Association and of the Medical Society of the District of Columbia, died in Washington, on August 13, at the age of thirty-nine years, from Rocky Mountain spotted fever contracted during the course of his investigation into the disease in Bitter Root Valley, Montana. As a result of his studies, which he had been conducting for the last two years, the disease has been almost entirely eradicated from the valley.

Dr. William I. Cowie of Guilford, Me., a graduate of McGill University Medical Faculty, Montreal, in 1895, died in a hospital at Bangor, following an operation for appendicitis on August 4, aged 43 years.

Dr. John F. Hilton of Phillips, Me., a graduate of the University of Vermont College of Medicine, Burlington, in 1892, died at his home of disease of the kidneys on August 1, aged 45 years.

Dr. Irving E. Kimball of Portland, Me., a graduate of the Medical School of Maine, Portland, in 1876, a member of the Maine State and Cumberland County Medical Societies, the Academy of Medical Science, and the American Laryngological, Rhinological, and Otological Association, and formerly on the staff of the Maine General Hospital, died at his home after a long illness on August 4, aged 60 years.

Dr. Albert Matson Belden of Northampton, Mass., a graduate of the College of Physicians and Surgeons, Baltimore, in 1888, and a member of the American Medical Association and the Massachusetts State and Hampshire County Medical Societies, died at his home on August 5 of pernicious anemia, aged 46 years.

Dr. William W. Moore of Summit, Miss., a graduate of the Eclectic Medical College, Cincinnati, in 1861, died at his home after a long illness on July 18, aged 74 years.

Dr. David M. Aronsohn, formerly of Glasgow, Mont., a graduate of the University of Minnesota College of Medicine and Surgery, Minneapolis, in 1905, died at the City Hospital in St. Paul on August 1, after a long illness, aged 35 years.

Dr. Edmund Marburg Rininger of Seattle, Wash., a graduate of the Marion-Sims College of Medicine, St. Louis, in 1893, and a member of the Washington State and King County Medical Societies, and of the American Urological Association, was instantly killed on July 25, when the automobile in which he was riding was struck by an electric train at a dangerous crossing at Riverton. Dr. Rininger was 42 years of age and was one of the most prominent surgeons of the Northwest.

Dr. Frederick F. Hoyer of Tonawanda, N. Y., a graduate of the Medical Department of the University of Buffalo, New York, in 1849, and a member of the New York State and Erie County Medical Societies, died at his home on August 15, after a short illness, aged ninety years.

Dr. Isaac Hull Platt of Wallingford, Pa., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1882, formerly a practising physician in Brooklyn and in Lakewood, N. J., and more recently engaged in literary work, the author of Bacon Cryptograms in Shakspere and other studies, and a member of the New York Academy of Medicine and the American Climatological Association, died at his home on August 14, aged fifty-nine years.

Dr. Henry Francis Borden of Brockton, Mass., a graduate of the Harvard Medical School, Boston, in 1869, a member of the Massachusetts State and Plymouth County Medical Societies, the Society of the Alumni of the Boston City Hospital, and the Brockton Medical Society, and consulting surgeon to the Brockton Hospital, died at his home, on August 8, aged sixty-seven years.

Dr. Henry J. Bruce of Bridgeton, R. I., a graduate of the Long Island College Hospital, Brooklyn,

N. Y., in 1874, died suddenly in his office on August 8.

Dr. John A. McCreary of Williston, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1886, died suddenly at his home on August 9.

Dr. Edmund C. Allard of Fond du Lac, Wis., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1893, died at his home on August 1, after a brief illness, aged forty-six years.

Dr. James Peterson McInerney of St. John, N. B., a graduate of McGill University, Medical Faculty, Montreal, in 1884, died in the General Public Hospital, St. John, on August 8, aged fifty-three years.

Dr. George C. Armstrong of Los Angeles, Cal., a graduate of the Northwestern University Medical School, Chicago, in 1899, and a recently appointed instructor in the University of California, died at his home, on August 4, aged forty-two years.

Dr. William Francis Fordham of Pensacola, Fla., a graduate of the Medical Department of the University of Alabama, Mobile, in 1875, died at his home after a long illness, on August 8, aged fifty-eight years.

Dr. Oscar C. Collins of Forsyth, Ga., a graduate of the New York University Medical College, New York, in 1860, and a member of the Georgia State and Monroe County Medical Societies, died at his home on August 5, aged seventy-five years.

Dr. B. L. W. Theodore Hansmann of Washington, a graduate of the University of Göttingen, Prussia, in 1850, who numbered among his former patients President Lincoln and Mr. Carl Schurz, died at his home, on August 13, aged ninety-one years.

Correspondence.

ZINC OXIDE AS A DEODORANT.

To the Editor of the Medical Record:

Sir:—In the course of treating leg ulcers at the Harlem Hospital by Dr. Oehs' method of dry zinc oxide, pulverized, followed by a wet boric acid dressing, we made a discovery that was rather surprising. We had a case that was particularly atrocious. The patient was a woman with three large, clean-cut ulcers on one leg in a markedly inflammatory area. On the other leg was a single ulcer, two and one-half inches in diameter. All these lesions emitted a terrific ordor—an odor so nauseating that it has on more than one occasion cleared the room of other patients and almost prostrated the nurse. This woman gave a positive Wassermann and luetin reaction, and for a long time we treated her along specific lines, all to no avail. She received one salvarsan injection, and after it the ulcers seemed to run wild, and the inflammatory zone became more extensive and acute. The ulcerations took on a more malignant aspect, and the odor, which we thought impossible of accentuation, grew positively unbearable. Driven to desperation, I suggested to Dr. Oehs that we try his method with zinc oxide and boric acid lotion, with little hope, it is true, but still with the fighting instinct to keep on trying. I filled the mephitic excavations with zinc oxide powder, flush with the surface of the surrounding skin, applied a bandage from toes to knees, and had the patient keep it wet with 10% of boric acid lotion. She returned after two days, and *mirabile dictu*, there was no odor whatever! The patient complained pretty bitterly of pain, but the odor was only a memory. The ulcers, too, were in very much better condition. We reapplied the dressing as before. She moaned with pain, but after two days more still greater improvement was noted in the appearance of the lesions. I am not giving at this time an outline of Dr. Oehs' treatment for these ulcers of the leg, which has appeared elsewhere over his own signature. I am simply calling attention to the remarkably deodorant qualities of the zinc oxide. The wet boric acid dressing was not the responsible factor, because it had been used before alone and the odor had remained as vile as ever. The result could be attributed to nothing but the zinc oxide. It might be worth while to remember this, for conditions might arise where other deodorants would be inadmissible, and zinc oxide could be employed with much satisfaction. Of course, it is possible that this effect of zinc oxide has been discovered by others. In that case it is not amiss to emphasize it and bring it to the attention of those who may have overlooked it.

W. P. Cunningham, M.D.,

Clinical Ass't N. Y. Skin and Cancer Hospital, Ass't. Physician Dermatological Dept., Harlem Hospital; Clinical Lecturer in Dermatology Fordham University.

PRIORITY IN THE USE OF SODIUM CARBONATE IN THE TREATMENT OF NEPHRITIS.

To the Editor of the Medical Record:

Sir:—In the *Medical Herald*, March, 1910, page 133, I published an article (which was not indexed) entitled "The Treatment of Chronic Nephritis With Sodium Carbonate (NA_2CO_3) and the Uremic Convulsions With Calcium," wherein I stated albumin and casts are lessened, edema is overcome, the retained phosphates and chlorides are thrown out, they being irritants to the kidney, blood pressure is lowered, and the symptoms are mitigated by the use of sodium carbonate; and convulsions are stopped by the use of lime water in the rectum, the calcium quieting the nervous system. The treatment of nephritis with sodium carbonate has been tried by German and American authorities with success, but credit has not been given to the originator—myself.

Chas. F. d'Artois-Francis.

951 St. Mark's Ave., Brooklyn, N. Y.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

B. M. A. MEETING AT LIVERPOOL—OTHER MEETINGS—EUGENICS CONGRESS.

London, August 2, 1912.

Medical gossip is largely concerned with the meeting of the B. M. A. The question whether the division into twenty sections is an advantage or otherwise depends on the intention of the individual attending. To the general public it is certainly not inviting to listen to two or three experts or rivals in any specialty thrashing out their differences or complimenting each other. This obviously accounts for the miserable appearance of some sections reported to me. The subjects of some on the other hand were well worth the consideration of all practitioners. The general meetings were occupied with political questions of a more engrossing kind than usual. They were dealt with by the representatives of the new organization which nominally controls the council and determines the policy. But neither

give complete satisfaction and there are constant complaints of misrepresentation. Not a few members would like to have a voice such as they had under the old constitution. But with the present conflict with government on hand they will do nothing.

Many interesting questions arose at the meeting, both in the formal proceedings and outside them, which are being talked over by returned members. The annual dinner, the amusements and the excursions are among them, but will hardly interest your readers, for I am assured they may all be summed up in the words "as usual" and "Liverpool equaled and even exceeded herself."

Dr. Robert Reutoul is a well known Liverpool man who for some twenty-five years has advocated a public medical service under professional control. Recent events have naturally enforced more attention to the matter and his particular scheme is being regarded more favorably. It would almost certainly be more acceptable than the government proposals and the results would probably be better. Nationalization of medicine, he believed, was not so far off as many supposed. There has been for a long period an increase in the number of medical officials and now the government is ready to provide 14,000,000 of the population with medical attendance. He thought the minimum payment demanded by the B. M. A. too small and would raise it to about 11s. To meet Mr. Lloyd George's objection he suggested that each insured person should contribute 1 penny per week, the commissioners to give 6s. and 2s. 6d. for medicines to either the chemist or doctor as agreed to in different localities.

There were objections put forward of course. Dr. F. Rees was shocked at syndicalist ideas being promoted in the profession. Members of any industry ought not to have full control of it, for they would do so in their own interests. The state should pay the profession, taking the funds from the well-to-do.

Mr. Ballance described a public medical service established and carried on in Norwich by the local profession. Dr. Wallace described a system lately arranged in Leicester. A number of suggestions were made as to the question of how far state control was necessary or desirable and both in the meetings and outside there was no little difference of opinion evinced.

In the Roman Catholic Pro-cathedral there was a special service at which a short address was given by Father Lucas, who hoped Liverpool would have a Catholic hospital with branches enough to accommodate every Catholic patient in the city. Hospitals have been established on many bases, but a sectarian one does not seem desirable.

There was a meeting of medical members of the Guild of St. Luke, a Catholic body, which made strong protest against the proposals of some eugenists for sterilizing the unfit. They held the human body to be sacred and inviolate. They thought degeneration in some cases admissible. But the causes of mental dificiency they held should be attacked in their relation to defects in our social organization.

The Irish Graduates held their usual convivial meeting—the luncheon or little dinner, according to the one who tells you the tale. They drank two toasts, the B. M. A. and their noble selves. At the first a guest wanted to discuss the policy of the association, but was finally suppressed by the chairman, who declined to allow any speeches beyond proposer and seconder. "I cannot permit any extraneous matter," said he. "But, Mr. Chairman," scornfully retorted the would-be speaker, "this is not a meeting of the British Medical or of the Primrose Dames."

A young man was introduced by Dr. Manson with the rare abnormality of transposed organs, his heart, liver, and stomach being each on the side opposite to the normal. He is not left-handed, is quite healthy, physically well developed, and is a member of the Territorial Force. Some *x*-ray photos of the visitor were taken.

On Monday Prince Arthur of Connaught opened the Health Exhibition of the Royal Sanitary Institute, which is an important feature of the annual meeting. It is held this year at York, the last meeting in that city having been twenty-five years ago. Nearly 600 delegates are expected from the army, navy, lunacy commissioners, and numerous sanitary associations and academical municipal bodies.

The Royal Institute of Public Health have held their annual meeting at Berlin at the invitation of that city. It is pronounced a success both as a scientific and social congress. The council announced that they had awarded the Harben gold medal to Professor Roux of the Pasteur Institute, Paris.

The first installment of statistics of the last census has been issued. It shows that on the census night there were more females than males.

On Tuesday the Lord Mayor presided at the meeting of the Hospital Sunday Fund held at the Mansion House. The distribution committee reported that £52,294 was available and that 257 institutions had applied for grants. It had been reported that one dispensary would participate in kinematograph shows held on Sunday, but it had not done so. They were informed that no grant would be given if it did, a natural decision considering that all the funds came from Sunday collections at places of worship.

The Lord Mayor had visited St. George's Hospital and found the account between the hospital and school was properly kept and the school did not take part of the subscribed fund beyond expense incurred for it. The distribution proposed was agreed to. Seven and a half per cent. was for surgical appliances and 2½ per cent. for district nursing societies.

The Parliamentary Committee on Patent Medicines has had brought before it by the White Cross League a number of objectionable advertisements of drugs and appliances taken mostly from provincial newspapers. Many are open incitements to illegal practices. Some vendors of these things distribute circulars concerning them by post or hand to houses throughout towns and districts. It is to be hoped the committee may see some way of checking this abuse.

The Royal Commission on University Education has issued a report of the evidence taken before it from October last to January, both months inclusive. Among the witnesses were the presidents of the royal colleges of physicians and surgeons and representatives of medical schools. The schools have done their work well, but the University of London too long acted as a mere examining body.

The International Eugenics Congress has been competing this week with the numerous other conferences held at this time of year for the attention of the press, the public, and the profession. As its name implies, it is really international, for France,

Italy, Germany, and Sweden sent its representatives to London, and one of the largest contingents came from the United States. The meetings were held in the University of London and Major L. Darwin presided. He defined eugenics as the practical application of the principle of evolution and declared that the nation which first took in hand the replacement of natural selection by conscious selection would lead in international rivalry. There was much talk on heredity and the effects of epilepsy, feeble mindedness, and mental as well as physical defects on the children of parents affected in these and other ways.

Dr. Raymond Pearl (of Main Experimental Station) contributed the results of investigations as to the fecundity of fowls and its inheritance in a paper which Professor Punnett of Cambridge declared to be the most important submitted to the congress. Professor Punnett himself considered the one point of eugenic importance that could for the present be controlled was feeble mindedness, which he apparently regards as a case of Mendelian inheritance. Dr. Weeks of New Jersey State Village for Epileptics said that sufferers from ordinary epilepsy lacked some element which was essential for complete mental development and the same was the case with the feeble minded. He laid down that if a father and mother were both either epileptic or feeble minded the child would be mentally defective; that epileptics in successive generations tend to become a larger part of the population; that normal parents of epileptics are not in reality quite normal and have descended from tainted ancestors. Professor A. Mooro of Turin limited the period of perfect development to the years from twenty-six to forty, when decadence began. Crimes of personal violence he found committed by the children of aged parents more often than by others. Insanity, too, was more frequent in children of parents too young or too old.

A rather remarkable paper was read by Schiller supporting the position that civilization is actually a degenerating force and that eugenics must be looked to for the counteracting influence.

Extravagant as this may appear, it is no measure of the claims put forward by these enthusiastic congressists for their favorite study, which from some of their statements might be supposed to lie at the base of all the sciences or at least compete with gravitation in the physical and morality in the spiritual sphere. In the papers brought forward the relations to public hygiene, history, militarism, civil and political economy were pointed out as of the greatest importance. As to education it should he under the control of eugenics, for which chairs should at once be provided in all universities to teach the coming generation. As to our art, it is touched in all directions, whether biological or pathological. Special are the relations with epilepsy, neuroses, and neurotic tendencies, degeneracy, alcoholism, mental defects, including insanity—in fact instead of being auxiliary to medicine eugenics would seem to claim to reverse the position.

Primary Carcinoma of the Lung.—A. T. Henrici states that this is a rare affection, occurring approximately once in sixteen hundred autopsies. (2) Probably the majority of so-called cancers of the lung are in reality of bronchial origin. (3) Squamous celled cancers of the lung probably arise in the majority of cases from bronchial epithelium which has undergone a metaplasia. (4) Some of these tumors apparently invade the lung along the alveolar wall, retaining the alveolar septa as stroma.—*Journal of Medical Research.*

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

REAPPEARANCE OF THE PLAGUE—AGE OF LEPERS—INCREASE IN GENERAL MORTALITY FOLLOWING CONTAMINATION OF THE WATER SUPPLY—A STUDY OF INFANT MORTALITY.

MANILA, June 28, 1912.

AFTER an absence of seven years among human beings, and six years among rats, plague was again found in the Philippine Islands on June 19th. A Filipino employed in Manila as a watchman at 635 San Jacinto, in the Chinese district, and who resided on Calle Antonio Rivera, was found dead in his home on the date mentioned above. The history of the case showed that he had been ill three days. On post-mortem examination, the typical plague buboes were found in the right groin and right axilla. Smears made from the spleen showed bi-polar staining organisms, and inoculations made into guinea pigs resulted in typical attacks of plague, and the organism which was recovered from the guinea pigs agglutinated with plague serum. The manner in which the infection was contracted is not known. The nearest known focus of plague is at Hongkong, and there is no evidence to show that this man had been out of the country during the past few years. Test examinations of rats are made regularly, at weekly intervals, throughout the year, and the reports on these have always been negative. Examinations of many hundreds of rats caught in the vicinity of the place where the man died, and where he worked, have failed to show any plague-infected rats.

The second case occurred on June 26th, in the person of a Filipino woman, aged 44 years. She was found alive, in her house, and had been ill for three days. At the time she was transferred to the San Lazaro plague hospital she had a temperature of 41° C. and was in a dying condition. The autopsy showed only slightly enlarged glands in the left groin. There was no macroscopical change in the spleen, nor were the other post-mortem findings of plague encountered. Smear preparations made from the glands, and from sections of the spleen, were gram negative, and showed bi-polar staining bacilli. Inoculations from this last case have been made into guinea pigs, but as yet it is too early to know the result thereof. This woman, from reliable evidence, had also not been out of the Philippine Islands during the past few years. In a nearby food store, where the woman is known to have purchased her food supplies, four dead rats were found. These were taken to the Bureau of Science for diagnosis. The post-mortem findings were negative, but material from suspected glands were inoculated into guinea pigs, and the results are being awaited.

In view of the fact that the death rate of the city is rather below normal, for this time of the year, and that the cases have occurred in residents of the city, would seem to indicate that the infection is not serious, and also that it was not introduced by human beings.

Speculating upon the mode of introduction of the disease, it seems most likely that it was introduced by sick rats which came in cargo, like crates of onions, potatoes, baskets of eggs, garlic, and similar food stuffs which arrive almost daily in large quantities from China, Japan, and other plague-infected countries. It seems quite possible that a plague-infected rat may have made its escape

from one of these containers after it arrived in Manila, and thus infected other rats. Three gangs of rat catchers have now been at work one week, and enormous numbers of rats are being caught, but, so far, no plague infection has been found among them.

An analysis of the ages of 2,556 lepers confined at the Culion Leper Colony gives most interesting results. There are three lepers under three years of age. The number gradually increases to the age of 17, at which age there are 63. The incidence, between 17 and 18 years of age, almost doubles itself, the number of lepers 18 years of age being 106. The largest number, 139, occurs at 21 years of age, and after the 24th year, at which there are 102 lepers, the number gradually declines until the 101st year, of which age there is one leper. Briefly, then, in the seven years which intervene between the seventeenth and twenty-fifth year there are 775 lepers, or almost one-third of the entire number that occur between the third and the 101st year, so that leprosy would appear to be a disease that has its greatest danger for early manhood and early womanhood. As to sex, the proportions which were recorded during the early years among the lepers of the Philippine Islands still hold remarkably true. Of the total number of 2,556, 1,629 are males and 927 are females, so that, approximately, one-third of the lepers are women and two-thirds men.

The recent experiences had in Manila with the mortality rates during the time that the water was being used from the Mariquina River affords apparently a striking confirmation of Hayem's theory. It will, perhaps, be remembered that Manila's water supply is derived from the Montalban reservoir, which impounds water from an uninhabited watershed, but owing to the unusually severe drought, the like of which has not occurred in the Philippines for over fifty years, this supply became exhausted, and the old (Spanish) source for water had to be resorted to. The use of the Mariquina water was begun on March 9th, and was discontinued on May 24th. Based upon an average of the deaths for 1909, 1910, and 1911, the normal deaths for March would have been 611; for April, 564, and for May, 585, or a total of 1,760. This year for March it was 814; for April, 767, and for May, 782, or a total of 2,363. This is an increase of 603 above the average rate. The increase in the number of deaths was found principally among the following:

	Increase.
Dysentery	18
Enteric fever	15
Tuberculosis of the lungs	33
Meningitis	15
Bronchitis, acute	114
Bronchitis, chronic	14
Broncho-pneumonia	99
Pneumonia	28
Diarrhea and enteritis	17
	353

It will be noted that over half the increase occurs in the so-called water-borne diseases—bronchitis, acute and chronic, and meningitis, also show a large increase, but, as past investigation has shown, these diseases are generally of a gastrointestinal nature and are misdiagnosed under the above heads, but the remaining 250 deaths occurred among general diseases other than the water-borne, and strikingly confirm Hayem's observations.

The increase in the death rate is also interesting because well-informed observers had concluded that, as the inhabitants that live above the intake do not create any sewage which finds its way into the stream and as there were no rains to carry surface drainage which might cause pollution, no increase in the death rate was to be expected. When it is remembered that the Montalban supply of Manila, which comes from an uninhabited water-shed, is not filtered, and has not been regarded as a very good water from a bacteriological standpoint, it is all the more striking that water taken from an inhabited water-shed, and which from a laboratory standpoint is not very much inferior, should show such a large increase in the death rate. During the period that the Mariquina River water was used a test was made of copper sulphate and of calcium hypochlorite in the Manila water supply, in the proportions of one to three million, in order to determine their value in reducing the number of bacteria present. Apparently, the calcium hypochlorite in the Manila water supply, in the proportions given above, had no marked effect. The copper sulphate showed marked germicidal properties. The average number of bacteria during the time the copper sulphate was used did not exceed, during the first week, 400 per cc. The second week there were, apparently, unusual sources of pollution present, because colon organisms were found three days in succession, and the bacterial count on one day reached the large figures of 4,900. There was then a rapid reduction until the number reached 1,000. Calcium hypochlorite was then used, and the number of bacteria rapidly increased to 4,000 per cc., and with one or two exceptions remained near the 3,000 mark during the entire period of 13 days during which this chemical was used. Copper sulphate was then again used, in the proportion of one to three million, and a rapid reduction in the number of bacteria took place. There were occasionally as many as 1,000, but the average number was about 500. Since May 24 water from Montalban alone has been used, and all chemical germicides have been discontinued, and the bacterial count, with one exception, has remained about at the same figures that obtained during the time that copper sulphate was being used in the Mariquina water.

The last legislature made provision for the appointment of a board to study the question of the high infant mortality, and to make a report to the next legislature upon its conclusions. The Governor-General has just issued an Executive Order naming Dr. W. E. Musgrave, chairman, and Dr. Manuel Guerrero and Dr. Proceso Gabriel, as members.

1. **Problems of Gastroenterology.**—W. B. Cannon states that observations on lower animals have revealed specially sensitive spots in the back of the mouth, afferent impulses from which liberate the sudden sequence of movements constituting deglutition. According to Kahn the spots are extraordinarily excitable by mechanical stimuli.

Recent investigations have also shown that throughout that part of the alimentary canal which is provided with smooth muscle a reflex is present such that a stimulus at any point provokes contraction above and relaxation below. This "myenteric reflex" is operative at the cardiac sphincter, for acid below, in the stomach, causes contraction at the cardia; it is operative at the pyloric sphincter, for acid in the stomach opens, and acid in the duodenum closes, the pyloric orifice; and the reflex is also manifested in the propulsive peristalsis, or diastalsis as the author prefers to call it, in the small and large intestines. The work of London and his associates indicates also that foodstuffs are absorbed at different rates at different parts of the tube—meat most in the upper part, starch and fat most in the lower part—and that in each portion of the tract, in the case of any particular food, a constant percentage amount is absorbed, quite independent of the amount fed. One of the most important investigations in the domain of gastroenterology is that which has indicated the fundamental importance of tonus for the movements of the alimentary canal. If the tonic state is absent, the movements will not occur; if the tonic state is too great, they will not occur; if there is a proper relation between the tonic state and internal pressure, i. e., if the proper tension is developed, then the various obvious movements naturally result.

2. Scorpion Stings and Their Treatment.—L. H. Mills presents a careful study of the effects of scorpion stings as observed by him in Mexico, and of their treatment. He has found that the sting of a scorpion can cause death in animals and in man. The effects produced by the sting of a scorpion depend upon (1) the species of scorpion, (2) the natural resistance of the victim, (3) his age, (4) his condition of health, (5) the time of year, (6) the degree of exhaustion of the scorpion's poison gland, (7) the time elapsing before treatment is received, (8) the treatment itself. Certain human beings appear to have a natural resistance to scorpion poison. There is no proof that immunity to this poison can be acquired by repeated inoculations. Scorpions' blood contains protective substances which render the scorpion immune to its own poison. These substances, if injected early and in sufficient quanity, aid markedly and promptly in relieving the urgent symptoms in human beings following scorpion sting. At present the use of scorpions' blood in quantity is impractical. It is not yet proven that the injection of the blood or of the extract of the bodies of one species of scorpion will aid in producing resistance to the poison of all other species. The conditions following severe poisoning by a virulent scorpion are, symptomatically and pathologically, those of a grave serous meningitis. The treatment of scorpion sting varies with the severity of the symptoms. In general it consists of: (1) Simple incision and the local use of evaporating lotions. (2) In severe cases, incision, combined with lumbar puncture, which may be repeated if necessary, and the repeated hypodermic injection of scorpion blood to total about 1 c.c. per kilo of body weight. (3) The internal administration of stimulants such as black coffee and aromatic spirit of ammonia, or hypodermic and rectal stimulation if the patient is unconscious.

3. Differentiation of Catarrh of the Large and Small Intestines.—A. E. Austin notes that diarrhea does not always indicate an intestinal catarrh nor does constipation exclude it. Nothnagel's classification is as follows: (1) Constipation with pure colon catarrh, (2) diarrhea with catarrh of the small intestine, (3) alternation of diarrhea and constipation, (4) usual number of stools daily, but these are mushy or pasty. The last two forms are more often associated with a combined catarrh of both divisions of the intestinal tract The microscope and colon washing have added much to the accuracy of this localization. If mucus is abundant, but no food remnants remain in the stool on microscopic examination, one is assured that the colon only is affected. If both food remnants and abundant mucus are present, one is not so sure of the involvement of the colon in the process. This one can ascertain by attaching a glass funnel to a colon tube which is introduced as far as water will flow through it—if passed too far it will reach the sigmoid and double on itself—and after pouring a pint of water into the funnel, letting it run into the intestine an dby lowering the funnel run out several times; practically no feces will come out, but if there is a colon catarrh, each time the water flows out, it will be found to be more and more filled with shreds of mucus, which float about in it. If one of these shreds be placed upon a slide and a little coloring agent consisting of a mixture of brilliant green, 0.6; neutral red, 0.3, and water, 30, be added, the mucus and the epithelial cells will be distinctly stained, the mucus red, and the cells, green, except the nuclei, if they contain them, which will be red again. This presence of nucleated cells is the best proof of the origin of the cells from the colon, since if they come from the small intestine the nuclei are usually destroyed by digestion.

1. The Proteins.—D. D. Van Slyke notes that the present conception of the structure of the proteins is due essentially to the work of Emil Fischer and of those who were either directed or inspired by him. Stating this conception briefly: the proteins are combinations of the $^{\alpha}$-amino acids which are linked together in chains by condensation between the carboxyl and amino groups of the different acids. That is, the NH_2 group of one amino acid and the COOH group of another combine with elimination of H_2O, and are bound together by a $-CO-NH-$ bridge, or *peptid linking*. Any number of amino acids can be thus, so to say, dovetailed to form chains of unlimited length, and such great molecules as we meet in the proteins. Every known property of the proteins is consistent with this theory, and while the structure of a single protein has not yet been worked out in absolute completeness, yet one may say that the existence of this type of structure in the protein molecule has been definitely proved by the methods of both synthesis and analysis. The first point required to prove Fischer's theory was demonstration of the fact that the proteins actually consist of amino acids in combination. Demonstration of the manner in which the amino acids are bound together forms the second step.

2. Physical Signs and X-Rays in Chest Conditions.—E. A. Miller and S. J. Quimby state that the cases in which radiology is especially valuable in making a diagnosis of pulmonary tuberculosis, before the disease may be determined by physical signs, may be classed as follows: group A, in which there are areas of infiltration; group B, in which scattering glands are infected. Under group A three areas are generally considered by diagnosticians, the apex or subclavicular fossa, the subscapular area or root, and the base. The subscapular area is more commonly the first area affected than has been generally noted. And in this area also the physical signs are more obscured by the chest wall. In some cases an extensive process on one side may be continued for some months with fibrosis, which has escaped notice till a more acute process on the opposite side calls attention to the case, and at such times the more

serious lesion gives no distinguishable signs. The cases in which a few miliary tubercles in various parts of the parenchyma are plainly visible usually give but a few râles and no impairment of resonance, but, as it is possible to show on the radiographic plate tubercles much smaller than a pea, and the appearance is quite characteristic, these cases form a most important part of this group. Several cases have also been encountered in which considerable areas of infiltration near the hilum with overlying normal or emphysematous lung tissue, gave no appreciable signs at the time of the first examination. In other cases conglomerate masses of appreciable size, in which one part was in the stage of infiltration, and other areas in the fibrous stage, so masked the physical signs when the lesion occurred near the base or around the heart border, or in muscular individuals, that the radiograph was the determining factor in diagnosis. Group B: While it has long been known from autopsy findings that a large proportion of the inhabitants of cities have at some time had an unrecognized tuberculous infection of some pulmonary glands, it is now possible not only to determine the extent of such infection, but also to observe an infiltrated area around their sharply defined border at an early stage when breaking down occurs. Another class of incipient cases in which the radiograph is valuable may be divided between groups A and B. In these cases the tuberculous process is secondary to, or superimposed on some other disease, as bronchitis or pneumonia.

4. The Cancer Question.—E. E. Hubbard reviews the various theories that have been advanced to explain the origin of cancer. He notes that in looking over the histories of more than a year's work at the General Hospital of Kansas City, Mo., he has found eosinophilia recorded in every case in which a differential count had been made. This suggests a possible parasitic origin of cancer.

2. Psoriasis Familialis.—F. C. Knowles concludes that psoriasis is not an hereditary disease. Very seldom is there found more than one case in a family. The author has been able to discover but six instances in hundreds of cases examined. Psoriasis familialis has been very little touched on in dermatological literature. The etiology of psoriasis is as yet to be ascertained, but cumulative evidence points strongly toward a parasitic origin.

3. Treatment of Psoriasis.—Winfield states that while the parasitic theory of psoriasis has much in its support, the belief that this disease is the expression of some disturbance in metabolism seems to be nearer to the solution of the problem. Acting on this supposition he has for some years been treating his patients with lactic acid and colonic irrigation, assuming that the intestinal autointoxication was an etiological factor of the disease. Lactic acid disinfects the alimentary canal by its antiseptic action; colonic irrigation washes out decomposing matters, stimulates peristalsis, improves the intestinal circulation, relieves passive inflammatory conditions, and increases the skin resistance by improving general health. Analysis of his cases, forty in number, is given by the author. In twenty-three cases the attack was cured and in sixteen there was improvement. Thirty of the cases had only lactic acid and irrigations; in the other ten chrysarobin ointment was also used. The general results were far better than when the other well-known measures were employed.

4. Relation of Aortitis to Syphilis.—By C. L. Cummer and R. Dexter. (See MEDICAL RECORD, June 8, 1912, page 1115.)

8. Acute Osteomyelitis of the Jaw.—W. W. Babcock states that osteomyelitis in the young occurs in the lower jaw as well as in the long bones of the extremities, although at a somewhat later age. Its early diagnosis is to be based on the early severe, systemic disturbance, and the widespread involvement of the bone. The prophylactic treatment consists in drilling the bone under aseptic precautions. After the formation of pus, free drainage should be employed which should be external if there be much necrosis. No teeth should be extracted nor should teeth which merely hang from attached mucous membrane be removed. Dead portions of bone should not be removed until entirely detached or until new bone capable of maintaining the contour of the jaw is formed. Separated and loosened teeth with gum attachment usually become reimbedded and serviceable.

12. Thrombophlebitis of the Left Leg.—By H. D. Kistler. (See MEDICAL RECORD, June 29, 1912, page 1250.)

18. Melanosarcoma of the Chorioid.—C. R. Heed and S. L. Olsho report a case of melanosarcoma of the chloroid, in which the condition was unsuspected by the patient for the time and unrecognized by the physician, the symptoms being those of iritis with diminished intraocular tension, whereas one would expect those of glaucoma with increased tension. The patient became blind in one eye from a blow by the fist, without suffering any ocular pain, except for a short time, until a year later. The onset of ocular pain was sudden, extending from the temporal side of the blind eye to the back of the head and rapidly grew worse. The correct diagnosis was made on pathological examination of the enucleated eye. The case emphasizes the necessity of enucleating blind eyes which are giving pain.

20. Full-Term Ectopic Gestation with Fetus Carried in Abdomen for Thirty-five Years.—F. N. Yeager reports the case of a woman, aged 72, from whom a fetus of a female child at full term was taken at autopsy. It was enveloped by a very tough calcified membrane, too hard to be cut with a knife, attached to the right ovary. The history of the case showed that the patient had expected confinement in August, 1877, and had evidently had an extrauterine pregnancy which then had come to term but was not operated on. The atrophied uterus was found firmly attached to the lower part of the cyst containing the fetus. The placenta, which was probably attached to the intestines, had evidently been absorbed, as no remnants of it could be discovered.

6. Observations on the Neuron. H. Campbell.

1. Integration of the Social Organism.—Sir T. Clifford Allbutt points out that the modern state is passing away from the dictatorial to the sympathetic stage. In the internal affairs of social bodies the people will no longer be guided by principles of unmitigated individual competition. Competition is now less between individuals than between states, between the several social organisms; and that state will survive which has the strongest internal coherence, the freest play among its units and the readiest sensitiveness to readjustment. Many things are coming about in a few years, by sympathy and the social soul, that by heredity could have been compassed only by the waste of generations. We were told on one hand that only by the slow eliminating process of the ages could persons who craved for alcohol be weeded out; yet what are the facts? In the span of the author's lifetime the social conscience has done more to weed out drunkenness than many a generation of the hereditary plough. For we inherit not form only; we inherit also the law of organic memory, a capacity of making habit; and this capacity in every man by the pressure and conventions of the social hive can be redirected and reinforced in geometrical ratio. How long does it take to convert an English or a German stock into an American? May not the same kind of disinterested motive and of formative memory do more than heredity to deal also with cripples, paupers, culprits, and moral and physical incurables of many sorts, and do it more quickly? Humanity has cared for the weak instead of eliminating them, under the instinct, which reflection is making clearer, that thus it is promoting the social coherence by which the survival of a nation is to be established.

3. A Municipal Dispensary and Tuberculin Treatment.—A. M. Fraser and H. Clark describe the lines of treatment that they have adopted at the Portsmouth municipal tuberculin dispensary. The cases are considered in seven classes: Class 1 ("contact").—Advice is given as to hygiene and safeguards from further infection if the individual is still living with an infective case. In a few cases with bad family history, a short course of tuberculin is given. Class 2 ("probably phthisical").—If symptoms are not relieved by attention to the teeth and hygiene a course of tuberculin is given. This has generally relieved the symptoms and encouraged the patients, and has often led to the discovery of a more urgent case among friends or relations who have applied in order to have similar symptoms relieved. Class 3 ("early, slight").—These cases are treated first at the dispensary, except in an occasional case where, for special reasons, it is inadvisable for the patient to remain at home. The majority are able to work and can be restored to health, and the disease arrested, without any further measures. A few cases fail to respond, and need to be sent to a sanatorium. Class 4 ("early acute").—These cases are generally supposed to need institutional treatment, and for a considerable number this is undoubtedly advisable. It is, however, surprising how many improve sufficiently with a few weeks' rest at home to attend the dispensary, and then do perfectly well without ever going away. Class 5 ("chronic, slight").—These patients do well at dispensary. Class 6 ("chronic, advanced").—This includes a variety of conditions, and it is difficult to generalize about them. Many do surprisingly well at the dispensary, especially if at some period of their treatment they can have a short stay at a sanatorium. Class 7 ("severe").—If hospital accommodation can be provided for these cases and tuberculin used when possible, some will be found to respond. Some of the most striking results are obtained in this class, but it must be remembered that it is in this class that every method of treatment, as also nature unaided, has obtained an occasional miracle.

4. Treatment of Habitual Dislocation of the Shoulder Joint.—E. D. Telford states that in dealing with a condition such as habitual dislocation, dependent as it is upon mechanical alterations in or around the shoulder joint, it is evident that no treatment short of operation will be of any value. Any appliance which may be designed to control the dislocation must involve a limitation of movement so great that the appliance becomes as irksome and intolerable as the disease itself. Assuming that operative treatment offers the only hope of success, the choice will lay between excision of the head of the humerus and the operation of capsulorrhaphy. Excision, although it appears to have given very good results, is a needlessly severe operation, and should not be adopted as the first line of treatment. It may be that some cases, in which the lesion is dependent on gross damage to the humeral head, will require excision, but in general the operation of capsulorrhaphy is the simpler and gives the better result. Capsulorrhaphy was first done by Gerster in 1883, followed by Bardenheuer in 1886, and was fully described by Burrell in 1895. The aim of the operation is to reef the overstretched portion of the capsule or, better, to excise a large oval piece and suture the raw edges together. The excision of a portion of the capsule has the great advantage that it allows of a free exploration of the interior of the joint. A review of the reported cases shows that the operation has given most satisfactory results; it has been done some forty times, and while there has been one instance of recurrence of the dislocation, there is no record of ankylosis or other damage to the joint.

4. Hospital Reform.—M. Dewar discusses the widespread abuse of the privileges of receiving free treatment at dispensaries. He advocates the following measures of reform: (1) A notice: "This voluntary hospital is for those who are unable to pay for medical or surgical treatment" should be placed in all out-patient rooms, and in the convalescent rooms of all the wards. (2) An official should be appointed to supervise the applicants for advice or treatment. This could be done by examining the lists of out-patients each day. Cases of sudden illness, accident, or emergency would not be inquired into till treated and progressing satisfactorily. No standard of wage or rental is suggested, as each case requires to be separately considered, and much would be left to the judgment of this official, under the advice of the medical officers, especially with regard to medical or surgical eligibility. Experience has shown that doubtful cases do not return when it is known there is an inquiry officer. More is expected from the presence of such an officer as a *moral force* than from any action resulting from his inquiries. (3) Evidence of suitability, except in emergency cases, should be obtained on two points: (*a*) that the patient cannot pay; (*b*) that

the case is suitable for hospital treatment. (4) Urgent cases should be attended on first application, and if eligible should be detained for further treatment, but if ineligible should be referred for treatment elsewhere. (5) Trivial cases, after having been seen to, should be referred elsewhere. (6) On first visit all patients should be seen by a registered medical practitioner. (7) The number of cases to be seen by a medical officer on any one day should be limited. (8) Special hospitals should only treat special cases of their kind. (9) Out-patient departments should be chiefly reserved for consultative purposes, and the cases referred back to the general practitioner with a statement of opinion. (10) Poor Law cases should be referred back to the Poor Law medical officer. (11) There should be co-operation of the hospitals in the same area with each other, and with public medical services and dispensaries, to prevent overlapping. Under the national insurance act this would probably become automatic, as all patients received at the out-patient department would have an explanatory note from the doctor for consultative purposes. (12) Notices should be posted in all out-patient departments calling attention to the public medical service or dispensaries.

6. **The Detection of Malingering.**—By A. G. Gullan. (See page 358.)

Münchener medizinische Wochenschrift.

July 30, 1912

Epilepsy as a Clinical Disease Conception.—Weber begins a study of this subject and first considers the individual components—convulsions, psychic crises and progressive deterioration. There are many sorts of convulsive manifestations which agree among themselves in being of brief duration and in being attended with loss of consciousness. Another attribute, of course, is involved, to wit, periodicity. A diagnosis cannot be made from one attack. The disturbances of consciousness also occur periodically, and are often wanting in the earlier years. There is more than a simple clouding of consciousness, for the entire conduct may be affected. The spirits are affected in different ways, patients being irritable or depressed. The mental processes are slowed. The mental state during these periods differs notably from the state before or after the latter. The so-called twilight state, however, is not peculiar to epilepsy. In the course of five to ten years the permanent, progressive mental impairment has become evident. Until this does appear we are not justified in speaking of genuine epilepsy. The disease begins in early life. No genuine cases ever set in after the age of thirty years. Not all early epilepsies are genuine—for example, those which develop in alcoholized young soldiers. Some genuine cases begin in very early childhood, others at the first school years, others about puberty. Evidence increases always of the association of epilepsy with histologic changes in the cortex but these the author regards as wholly secondary in most cases. There are exceptions in which the lesions could not have been secondary, for the disease was too recent of evolution. One is cited of a three-year-old boy with unilateral convulsions followed by paralysis, due to encephalitis. The case became one of typical epilepsy, death taking place from status epilepticus in four years. Throughout the convulsions were more pronounced on the left side. Back of all this, however, is convulsibility. Else why do not all cases of encephalitis, meningitis, etc., become epileptics? The article will be continued.

Toxemia of Pregnancy and the Cause of Labor.—Franz, like others, sees an intimate connection between some principle in the blood of the gravida at term which sets up uterine contractions and another principle or group of principles which causes what is termed gravidity toxicosis. In both cases a disintegration of blood albumin is the cause of the toxemia. Of much interest are the unusual degrees of this toxicosis, the visceral degenerations. But we are unable to state yet which is cause and which effect. Is the toxic albumin derived from the visceral degeneration or is the latter due to the former? The author seeks to show that the blood state precedes the visceral change and cites many parallel figures to prove this sequence. The tables give values for albuminuria, edema, urinary toxicity, etc. If the kidneys are sufficiently crippled the phenomena of retention of urinary toxin are superadded. The element of anaphylaxis must also be reckoned with in connection with the toxic decomposition of blood albumin. This element is believed to determine the onset of normal parturition. The actual agent which causes the anaphylaxis and its blood changes is believed to be the placental albumin.

Deutsche medizinische Wochenschrift.

July 25, 1912.

Thyreosis and Anaphylaxis.—Wolfsohn shows that extensive analogies exist between hyperthyreosis and anaphylaxis. Recent studies are tending to show more and more a correspondence in the blood pictures of the two conditions. At least four points of concordance are noted, viz.: leucopenia, mononucleosis, eosinophilia and delayed coagulability. Other points of resemblance are seen in vasomotor excitability, dermographism, urticaria, and transient edema; outbreaks of sweating; bulimia; vomiting and diarrhea; anxiety, hot flushes, tremor, pareses, convulsions, cardiac palpitation, tachycardia, asthma-like attacks, and hemorrhages of the mucosæ. The conclusion seems inevitable, then, that hyperthyreosis *is* an anaphylaxis. Graves' disease of the thyroid, whatever it is, results in the production of a heterologous albumin. Conversely in anaphylaxis of exogenous origin there should be a hyperfunctioning of the thyroid, and perhaps of other glands of internal secretion. This can be almost mathematically shown in iodine anaphylaxis which results in thyreoses. Iodine anaphylaxis does not result if the thyroid is able to detoxicate this substance. In endogenous anaphylaxis from hyperthyreosis it is probably the iodized albumin which behaves as a heterologous albumin. In Graves' disease this iodized albumin is produced in excess.

Alimentary Galactosuria in Neuroses and Hepatic Diseases.—Hirose of Tokio refers to the fact that galactose is more difficult of assimilation than the other dietetic sugars, and is therefore a good measure of carbohydrate tolerance. The limits of assimilation in the fasting state vary from 20 to 40 gm. daily, while that of cane sugar is nearly tenfold as much. It has long been known that subjects with hepatic cirrhosis and catarrhal icterus show very low tolerance for galactose and as there are many cases of hepatic diseases in the author's clinic, a series of tests was made. After fasting with especial reference to cow's milk 25 gm. chemically pure galactose were given, the urine being submitted to a number of tests for this sugar. Twenty-two patients with some form of hepatic disease were examined. Galactosuria was present in cirrhosis and catarrhal icterus, but also in cancer of the liver, cholelithiasis and passive congestion. Hence this test possesses no specific value, but may be a good measure of hepatic insufficiency. The author also tested the reputed tendency to alimentary glycosuria in neuroses and Graves' disease in another series of twenty-two cases. Tolerance was poor in a series of Graves' disease and in neurasthenics. The point is at once suggested that these hepatic cases may have had neurasthenia, or rather that the sugar phenomenon may have had a nervous mechanism; while conversely, the author holds, those neurasthenics who show marked intolerance may suffer from hepatic insufficiency.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

THE EYES.—Reference to the pupillary reflexes and nervous affections of the eyes will be found in a previous section on the Nervous System.

A large percentage of applicants have ordinary errors of refraction, usually corrected by glasses, which are not of sufficient consequence to report. Actual blindness of both eyes should be reported, as such risks are rejected. In the case of a recent enucleation, the examiner should ascertain the cause and whether the other eye is in danger through sympathetic affection.

Double cataract will usually call for rejection of the risk until after complete recovery from an operation for extraction and a fairly good restoration of the sight. Unilateral cataract is not commonly considered a bar to insurance, if of long standing, if no recent increase in size, if no operation is contemplated, and if the other eye is normal. A cataract of recent appearance leaves more doubt as to the way it is going to conduct itself and whether or not the other eye will be invaded, than one of longer standing.

Subjects with chronic trachoma are not regarded as satisfactory risks and severe cases may meet with refusal. This condition, therefore, should be fully described.

These are the affections the examiners are liable to meet, and, after making a full report, they would better leave the final decison to the home office.

THE EARS.—Chronic deafness without any discharge during the past one or two years will not be a bar to insurance, though it is customary for most companies to charge a slightly increased premium owing to the greater danger incurred in the streets. Deafness should, therefore, be reported with the following details: If not total, can the applicant hear conversation and ordinary street sounds without the aid of artificial appliances? Is there any existing disease of the ear? Is there any history of discharge? If so, give date of last discharge.

There is a slight difference of opinion among the companies in regard to the acceptance of subjects with present or recent otorrhea. It may be generally stated, however, that these risks are insurable if there is no family taint of tuberculosis and favorable answers are received to the following queries:

Is the disease unilateral?

Is the discharge ever purulent, bloody or foul smelling?

Any pain or tenderness?

Furthermore, as the examination of the middle ear is a difficult matter and only of value when made by one with experience in this line, the applicant will be expected to furnish a certificate from a competent aurist comprising answers to the following questions in the case of present or recent otorrhea:

Size of perforation in the drum?

Site of perforation (upper, middle or lower portion—good drainage of the cavity depends upon the site of the opening)?

Any granulations, polypi, caries or involvement of the mastoid cells?

THE SKIN.—The diseases of the skin usually coming to the notice of the examiner are eczema and psoriasis. These troubles are of no importance unless they are persistent and invade large areas, in which case they are often the outward expression of some considerable dyscrasia or constitutional disturbance that may lead to lesions of the viscera and vessels at some future time. For this reason a company may believe it advisable to limit the applicant to an endowment or rated up policy. The examiner, then, should always give the nature, duration, severity, parts effected and the extent of surface involved.

Whenever a skin lesion presents itself, the examiner is expected to go into the case very carefully for the purpose of excluding syphilis, and he should also state that he has done so in his report, whether there is any suspicion or not, so that there will be no doubt in the minds of the staff at the home office.

Scars.—The origin of scars should always be ascertained and reported. The possibility of tuberculosis, syphilis or wounds received in some fracas should be kept in mind while making this inquiry.

MOUTH, TEETH AND TONGUE.—These parts should be looked at, as some indication of digestive disturbances, syphilis, or disease of the nervous system may be discovered which will suggest the advisability of further investigation. The applicant should always be requested to protrude the tongue, so that any tremor of the organ may be detected.

DEFORMITIES.—The loss of a finger or toe is only worth recording as a mark of identification. In the case of an amputation, the point of amputation, date, cause and present condition of the stump should be noted in the report. Always report the fact if the applicant uses artificial limbs, crutches or a cane on account of an amputation of the lower extremity or any other disability.

Curvature of the Spine.—The insurance value of a risk with spinal curvature depends on two conditions:

1st—Was the cause of deformity tubercular or nontubercular?

2d—Is the deformity sufficiently marked to cause undue pressure upon the viscera?

The antero-posterior spinal curvature (kyphosis) is commonly the result of Pott's disease or tuberculosis of the spine, especially when angular. The angularity is often better felt than seen. These cases should be accurately described, as they will usually be rejected at the home office.

Lateral curvature (simple lordosis and scoliosis) will not cause rejection in most companies unless too marked. The authorities at the home office will not get a clear idea of the amount of deformity unless the examiner gives the amount of deviation from the median line by actual measurement as well as other details. Some form of policy will probably be issued to subjects with lateral curvature if the displacement of the bony structures is not enough to cause excessive pressure upon the vital viscera.

Hip Joint Disease.—Having given a full history, the amount of shortening should be ascertained by actual measurement and, at the same time, an inspection should be made for the presence of scars which would indicate that an abscess formed when the disease was active. When possible to obtain a statement from the physician who treated the disease in its early stage this may have to be furnished in order to find out if there was any suspicion of tuberculosis.

The Medical Section of the American Life Convention will meet at the La Salle Hotel, Chicago, Ills., on Tuesday, September 3, 1912. At the meeting the following papers will be read: "Methods of Uranalysis Applicable to Insurance Examinations," by S. H. Baxter of the Northwestern National Life Insurance Company; "Prognostic Significance of Albuminuria and Casts," by C. Nauman McCloud of the Minnesota Mutual Life Insurance Company; "The Wassermann Reaction and Its Value in the Detection of Syphilis," by Amand Ravold of St. Louis; "The Selecting and Training of the Medical Examiner," by E. A. Babler of the International Life Insurance Company. The secretary of the Section is Dr. F. L. B. Jenney, 168 North Michigan avenue, Chicago.

The Detection of Malingering.—A. G. Gullam states that one cannot overestimate the difficulty and importance of making a diagnosis of malingering. Just as the physician should never diagnose hysteria until he has excluded by most careful examinations all forms of organic disease, so should all possible injury and its effects be excluded before the diagnosis of malingering is made. The difficulty of the detection of this condition is greatly enhanced at the present day by the modern press describing in detail ailments and their effect, and by the workingman being often well coached in the symptoms of some brother workman who has been disabled. For the sake of convenience the author divides malingering into three distinct groups, with the following definitions: (1) Feigned sickness or pretended disablement in order to avoid duty and obtain pecuniary benefit. (2) Sickness or disablement produced or prolonged by the individual in order to avoid duty and obtain pecuniary benefit. (3) Sickness or disablement in which the cause is feigned (that is, a false cause is given) in order to obtain pecuniary benefit. Undoubtedly the most difficult cases to eliminate from malingering are those of true traumatic neurasthenia or nervous shock, and it is sometimes very difficult to draw the line of demarcation between these two conditions. The utmost care should be taken in making the diagnosis of either of these conditions, in order that justice may be done. In traumatic neurasthenia definite symptoms of neurasthenia or hysteria are to be found; and there is usually a definite history of direct trauma often causing cerebral or spinal concussion; though sometimes this condition follows a psychical disturbance, such as serious fright. Moreover, not infrequently the patient has a neurotic diathesis, or is an alcoholic subject, or is over 50 years of age. In many of these cases there is some definitely localized hyperesthetic spot, which is quite fixed at the time of examination, and other distinctive manifestations of neurasthenia or hysteria will be found—such as patches of hyperesthesia or anesthesia, paralysis or paresis not limited to nerve distribution, tremor of eyelids or hands, hyperesthesia of the scalp, absence of corneal or conjunctival reflexes, psychical disturbances, etc. In malingering there is one feature which is invariably present—that is, the man is most emphatic as to his "inability to work."—*British Medical Journal,* August 3, 1912.

The Medical Examiner and the Company.—Mr. T. W. Blackburn, Secretary American Life Convention, in discussing the relation of the medical examiner to the contract criticised the ordinary medical examiner somewhat severely. He had observed that the ordinary examiner does no more than the blank makes necessary and that he often guesses at the information which is required to prevent the blank from being returned for correction. It is this personal knowledge of the carelessness and indifference of many physicians which leads some well informed solicitors and some skilled executives to say that if they could remove from the agent the incentive to put through a risk to earn a commission they would rather have the opinion of a live insurance agent upon the insurability of the average applicant than to rely upon the carefully billed medical blank even after it has been approved by the home office medical department. In visiting the companies Mr. Blackburn said that he had constantly met the inquiries, "How are we to improve the grade of medical examiners? How are we to escape the moral hazard of the family physician? What can we do to make the local examiner appreciate his responsibility? How are we to guard against collusion of physician and applicant? What system of inspection can be devised which shall detect the frauds perpetrated through the carelessness, ignorance, indifference, cupidity, and lack of moral courage of the local physician?"

The answer is as follows: Impress upon the examiner the nature of the contract as a commercial proposition; teach him in the schools first and in occasional conferences that the ethics of a noble profession require absolute frankness and unswerving honesty to the company; information by frequent communications from the home office that the life insurance contract is not a stipulation for a donation to the widow and orphan but a legal obligation between insurer and insured with terms equally binding upon all parties and privies; show him the importance of his relation to the contract from the standpoint of the principal obligors thereunder and educate him in the details, so that he shall give to the preparation of his application blank that same intelligent, painstaking consideration and attention which he knows he must give to diagonsis and prescription; emphasize always the incidental fact that the company pays him a larger fee for the professional service he is called upon to render than his average patient.—*Second Mid-Year Meeting of the Medical Section of the American Life Convention,* February 28, 29, March 1, 1912.

German Pension Hysteria.—Professor Bernhard delivered a lecture a short time ago before the Association of Iron Founders at Berlin in which he pointed out that in the minds of the masses the idea had been formed that every illness, every accident, must lead to a pension. In consequence people's attention was becoming morbidly concentrated on the processes going on in their own bodies. This produced those nervous phenomena which physicians described as "pension hysteria." Professor Bernhard said the disease was now epidemic in all the industrial regions of Germany. This debilitating collateral effect of workmen's insurance had in consequence of the accommodating attitude of the law courts attained dimensions so great that institutions with which it had been hoped to produce vigorous, happy human beings threatened to lead to the degeneration of the nation. Through excess the idea of protecting artisans was actually resulting in injury to them.

National Insurance for Russia.—According to the *Lancet,* Russia, following the example set by its western neighbors, proposes to introduce, at first on a limited scale, a scheme of compulsory insurance against sickness, and a bill to this effect is likely soon to become law.

Book Reviews.

An Index of Treatment by Various Writers. Edited by Robert Hutchison, M.D., F.R.C.P., Physician to the London Hospital, and Assistant Physician to the Hospital for Sick Children, Great Ormond Street; and H. Stansfield Collier, F.R.C.S., Surgeon to St. Mary's Hospital; Joint Lecturer on Surgery in St. Mary's Hospital Medical School; Surgeon to the Hospital for Sick Children, Great Ormond Street. Revised to conform with American usage by Warren Coleman, M.D., Professor of Clinical Medicine and Applied Pharmacology, Cornell University Medical College; Visiting Physician to Bellevue Hospital, New York. Sixth Edition, revised and enlarged. Price $6.00 net. New York: William Wood and Company, 1912.

The six editions that have rapidly followed one another since this work first appeared, less than five years ago, amply testify to the favor with which it has been received. This popularity is to be attributed to its eminently practical nature; to the compactness and ready accessibility of its subject-matter, and to the high standing of its authors. The latter include a large number of the best-known clinicians in the British profession, among whom may be mentioned Sir T. Clifford Allbutt, Bannatyne, Byrom Bramwell, Sir Thomas Smith Clouston, Goodall, Hunter, Hutchison, Morison, Lockhart Mummery, Sir Thomas Oliver, Poynton, Saundby, Sir James Sawyer, Sequeira, Eustace Smith, Purves Stewart, Norman Walker and Samuel West. The entire domains of medical and surgical treatment (with the exception of the more elaborate surgical operation) have been covered and have been included within the remarkably compact compass of 1051 pages. The subject matter, however, is presented in more than a synoptic manner, owing to the fact that only those methods of treatment are described which have been found to be the simplest and most effective. The present edition is a thorough revision, with the inclusion of many new topics, such as puerperal sepsis, hydro-, photo-, and thermotherapy, and treatment by carbonic acid snow. In the American edition the English prescriptions are adapted to the United States Pharmacopœia, and in these instances in which the preparations of the British Pharmacopœia have no exact equivalent in America, the composition of the British preparations is given in an appendix. The latter contains also brief descriptions of preparations commonly used in Great Britain but comparatively unknown in America. The general practitioner will find this work one to which he may turn for guidance in the treatment not only of the rarer conditions such as myoclonus, acromegaly, etc., but also of the common ailments, such as hiccough, insomnia, etc. There are 67 illustrations that admirably supplement the text. The paper, typography, and binding maintain the high character of this work which may be recommended without reserve to the general practitioner and to the student.

A Dictionary of Medical Diagnosis. A Treatise on the Signs and Symptoms Observed in Diseased Conditions. For the use of Medical Practitioners and Students. By Henry Lawrence McKisack, M.D., M.R.C.P. Lond.; Physician to the Royal Victoria Hospital, Belfast. Second Edition. Price $4.25. New York: William Wood & Company, 1912.

It is doubtful whether any one except the author, and possibly the proofreader, has ever read a dictionary from cover to cover. Yet the task is not an insuperable one even for the general reader, and under certain conditions such as the dearth of other literature and the desire to fill in the gaps in one's knowledge of philology this task may be attended with both pleasure and profit. At any rate, "A Dictionary of Medical Diagnosis" is a dictionary only in title and in the alphabetical arrangement of its subject matter. The reader need have no hesitancy in setting out to read this book as he would any other well-arranged treatise, for his interest will be maintained until he has finished the volume. This maintenance of interest is to be attributed to the author's delightful style and to his belief in the value of studying the various morbid phenomena strictly from the observer's point of view. To the student who would approach this subject from a path different from that of the regular textbook in diagnosis, and thus by this very novelty increasing his interest and aiding his memory; to the general practitioner who would gather together the scattered threads of knowledge gleaned from his student studies and subsequent reading; and to the trained clinician, who would fain discover any gaps in his own extensive knowledge of symptoms and physical signs, this book cannot fail to be a valuable one. The present edition includes a description of the newer diagnostic signs, such as Grocco's, Ewart's, Biernacki's, Joffroy's, Quinquaud's, Rotch's, Weber's, etc.; and of the newer tests or reactions, such as Salomon's, Cammidge's, Boas's, von Pirquet's, etc. The work is exceptionally well printed, the black-face side headings and important words in the text, and the numerous tables aiding in the use of this book for didactic purposes and for quick reference. The numerous illustrations are particularly helpful. The special articles on the Wassermann reaction, by Houston, and on the radiography of the abdomen, by Rankin, have been rewritten and amplified; and an article by MacIlwaine on the antiformin method of examining for the tubercle bacillus has been introduced. The index has been revised and enlarged. The work is one that will be found most serviceable by both student and practitioner.

Compendium of Diseases of the Skin. Based on an Analysis of Thirty Thousand Consecutive Cases; with a Therapeutic Formulary. By L. Duncan Bulkley, A.M., M.D., Physician to the New York Skin and Cancer Hospital; Consulting Physician to the New York Hospital; Consulting Dermatologist to the Randall's Island Hospital, to the Hospital for Ruptured and Crippled, and to the Manhattan Eye and Ear Hospital, etc. Fifth revised edition of the Manual of Diseases of the Skin. Price $2.00. New York: Paul B. Hoeber, 1912.

This little work has long been known as a most useful guide to the general practitioner. It represents the personal views and experience of the author; and it is to this personal element that the book owes much of its value. The subjects of diagnosis and treatment receive special attention. The therapeutic formulary, at the end of the book, contains a very complete set of prescriptions; in a subsequent edition, however, some of these prescriptions should be altered to conform with modern pharmacopœial nomenclature. Under the treatment of syphilis, salvarsan receives very scant mention; perhaps this is meant as a reaction from the very fulsome notice which this new remedy has received from the lay and medical press. The book is well printed, of convenient size, and contains all that the recent graduate requires on the subject of dermatology.

Gundriss der Biochemie für Studierende und Aerzte. Von Prof. Carl Oppenheimer, Dr. phil. et med., Berlin. Price 9 marks. Leipzig: Georg Thieme, 1912.

The plan followed by the author in this volume of 400 pages is somewhat different from that usually employed in small books on this huge subject. Only the more important topics have been selected, but the discussion of these has been made so full as to be really comprehensive, and an especial effort has been made to emphasize the facts and principles that serve to correlate the various aspects of the subject as a whole. Consequently one does not find the usual mass of analytical data, and all extensive consideration of methods has also been omitted—very wisely in the opinion of the reviewer, for when such information is desired it will always be necessary to refer to the large reference works. . Abbreviated descriptions of methods especially are worse than useless, and are much better replaced by more important matter. The first portion of the book is more distinctly chemical and deals with the composition and relationships of the substances making up the body. This section also includes three interesting chapters on the ferments and their biological significance. The second half of the text is physiological in character and contains admirable discussions of the processes of metabolism and nutrition considered from the standpoint of the newest researches.. Recent work in physical chemistry as applied to cellular activity, the nature and functions of the internal secretions, etc., is summarized and well presented so as to be easily understood by the ordinary medical reader. The book carries out its author's purpose excellently, and we hope that an edition in English will soon appear.

Zwei Yahre Salvarsantherapie. Herausgegeben von P. Ehrlich, F. Kraus, A. v. Wassermann. Redaktion: Fr. Kevsser. Sonderabdruck aus der *Zeitschrift für Chemotherapie und verwandte Gebiete*. Leipsic: Verlag von Georg Thieme, 1912.

This brochure consists of papers by Alt, Schreiber, Benario and Gennerich giving their experiences with salvarsan in the two years since its introduction. In addition Fordyce of New York, Emery of Paris, Iversen of Russia and Ascoli of Italy give a concise review of the literature on salvarsan that has appeared in their respective countries. The brochure should be useful to those who have not been able to follow the current medical literature on salvarsan. Otherwise it contains nothing new

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Forty-Sixth Annual Meeting, Held at Spring Lake, June 11 to 13, 1912.

Dr. Daniel Strock of Camden, President, in the Chair.

Blindness in Children.—Dr. D. E. English of Summit reported having examined thirty-one blind children during the past year. The cases had all been blind some time before being seen by him, and most of the histories were furnished by the family physicians. He gave the causes of blindness in the thirty-one cases as follows: Ten were born blind; five were found to be blind three years after birth; two were blind at one year old, following eczema of the face; two gave no previous history; in one blindness followed convulsions at two years old; in one cataract gradually developed after birth; one was found when a few months old and was blind at that time; another was blinded by the thrust of an umbrella when three years old; four became blind after measles; in one ulcer of the cornea produced blindness at six months; one, an epileptic idiot, became blind at six months; another was made blind by infantile paralysis at two years of age; and one became blind soon after birth from gonorrheal ophthalmia. No history of inflamed or discharging eyes could be obtained in any but one case.

Oration in Surgery—Prevention and Unnecessary Surgery Based Upon Investigation of the Early Symptoms of Surgical Diseases and the Comparatively Inferior Results of Late Intervention.—Dr. John Colt Bloodgood of Baltimore, Md., stated that by preventive surgery he meant measures which would make later operative interventions unnecessary, or minor operations which would save the patient from the secondary complications for which there was no surgical relief. He felt that the factors in unnecessary surgery were less remote than in preventive surgery; and, were more within the reach of early correction. He believed that late intervention in acute surgical lesions was unnecessary and avoidable. In this group, he classed delayed surgery as unnecessary surgery. He advised the education of the public in seeking advice of physicians early, and demanding that methods of precision be employed in diagnosis. Dr. Bloodgood felt that physicians should become better diagnosticians, and said that surgeons should be trained to do their part, to operate when such a course was indicated.

Vaccine Therapy.—Dr. Gordon K. Dickinson of Jersey City asserted that in order to have success in vaccine treatment, three conditions should obtain: First, the germs inducing the lesions should be discovered in the patient, and an autogenous vaccine be made from them; second, there should be sufficient arterial and lymph supply to the affected tissue, in order that the serum might reach it; and third, the lesion must be so localized, without complicating bacteriemia, as not to have exhausted the antibody-forming organs. Without a proper combination of the three factors mentioned, and rational application, vaccine therapy would fail and be discredited. Dr. Dickinson emphasized the necessity for accurately measuring the doses and properly spacing the time, and stated that if the dose were too great or too small, the results would prove unsatisfactory, and often dangerous.

The Doctor and Eugenics.—Dr. Thomas W. Harvey of Orange felt that the study of eugenics was of great importance to the doctor, because of its value as a scientific study, and because of the necessity for skilled technicians in the application of the principles to every day life. He considered the study of heredity important in that connection, and the effects of environment on hereditary tendencies. He thought special attention should be paid to the sterilization of the unfit, the granting of certificates of health to those about to marry, education in sex hygiene, matters of improvement of the race, and the removing of the ban of professional secrecy regarding social diseases.

Dr. D. F. Weeks of Skillman spoke of the efforts institutional physicians were making to collect data bearing on the subject of defectiveness, and asked the help of all toward that end. It was his opinion that New Jersey was at the head of all the States in that important movement. He stated that a law had been passed requiring physicians to report all cases of feeblemindedness and epilepsy, the same as contagious diseases, and that the State would give the assistance of an expert in deciding the important question of who was feebleminded, when needed. He believed that the foundation was being laid for good citizens in New Jersey; but stated that Austria had the best system, so far as marriage was concerned. Persons there contemplating marriage had to go before a board and pass an examination, similar to one for insurance in this country.

Dr. F. D. Gray of Jersey City did not believe there was a chance to do much for this generation in the way of bettering the human race, and that such improvement as we wanted would have to be worked for in future generations. While he favored a Sterlization Board, yet he felt that the children should be educated in the home to know what led to pure and clean progeny, and said that the physician was the person to test this out.

Dr. W. M. Leszynsky of New York City mentioned the method of teaching sex hygiene as conducted in the New York City schools, and said that a large portion of the population of our country were incapable of teaching their children hygiene; that such instruction should be in the hands of skilled physicians only; and that neither children nor adults should be taught on a biological basis. He felt that in the sterilization of criminals, there was danger of establishing a class of male public prostitutes.

Dr. Chas. A. Rosenwasser of Newark said that this was one of the problems that would never be solved, because when we said that by prohibiting the marriage of the unfit, we would improve the race, we were mistaken, for marriage was not absolutely necessary for propagation. He felt that this would not be stopped as long as the sexual instinct was the most powerful possessed by the human race. Education sounded well, but what would you teach the people? he asked. The best scholars disagreed on that subject. While one said that we must limit our offspring, yet the law said that we must not. Dr. Rosenwasser said that if we knew just what to teach, we should gain nothing, and he gave as an example the fact that no one knew better than doctors and nurses the danger of the drug habit, yet the larger number of such drug fiends to-day were from those two professions. He advised the solving of the problem of what normal sexuality was, before attempting to teach the families and children about it; and suggested that too much enthusiasm should be avoided.

Dr. Geo. H. Balleray of Paterson was inclined to look upon heredity as the important factor, and said that there was much less attention paid to the breeding of the human race than to that of hogs; that a man showed more prudence in buying a horse than in selecting a wife; and that a woman exhibited more discretion in buying a hat than in the choosing of a husband. He advised that marriages should be based on the principle that no one but the fit should be allowed to propagate the species, and did not favor especially the teaching of sex hygiene. What was wanted was a sound mind in a sound body, he said, and that could be obtained only by proper selection. He advocated the New Jersey State Medical Society's putting itself on record as opposed to the Government's opening her doors to the importation of the rabble and scum of Europe, and said that there was no reason why America should be the breeding ground for the mentally and physically unfit. If that were prohibited, a great deal would have been accomplished.

Dr. Harvey mentioned that he had been told that there were laws covering the production of illegitimate offspring, but that they were not very well enforced.

An Analysis of the Refracting Optician Evil: An Appeal to the General Practitioner.—Dr. Linn Emerson of Orange said that the refracting optician, despite his claims to the contrary, was grossly incompetent, though he was making a strenuous fight for legal recognition. Dr. Emerson felt that the general practitioner who permitted his patients to go to the refracting optician was guilty of great folly. He advocated the use of drops by the general practitioner, and said that glasses could not be properly fitted in the young without them. It was his opinion that the fitting of glasses was as much a branch of general medicine as minor surgery was.

Cyclic Vomiting in Children.—Dr. Frank R. Sandt of Paterson, through his long experience with such cases, was convinced that cyclic vomiting was a disorder found only in children of the so-called nervous temperment, and in those who had inherited the neurotic tendency from their parents. He felt that cyclic vomiting was primarily due to the effect of certain exhausting or depressing influences exerted on the nervous mechanism of the digestion; that intestinal toxemia was secondary; and that the best lines of treatment were followed when attention was directed to the general physical well-being of the patient, rather than to the alimentary tract, exclusively.

Dr. Henry Chavanne of Salem had had several cases of cyclic vomiting which he had handled successfully, and said that he had used a tablet of codeine in a specific quan-

tity of water, giving a teaspoonful every hour until the effect of the codeine was evident and the child rested.

Dr. Sandt observed that the general effect obtained from the use of bicarbonate of soda was that the child's system became accustomed to it after a few attacks, when it was only good as a stimulant. He favored the idea of the specific history, and said that his cases had been among the more highly cultivated people, in whom there had been a nervous strain at some time. The cases seemed to be limited to the age before puberty, he stated

Diagnostic Pitfalls.—Dr. Richard C. Cabot of Boston, Mass., spoke of his experience during the past ten years at the Massachusetts General Hospital, and of his work there in studying some three thousand autopsies, which gave a basis of knowledge that was very secure, though not wide. The work was done in the clinic; those who attended received history sheets, containing the results of the physical and laboratory examinations, as well as the history proper of each case. Dr. Cabot, himself, did not know the outcome of a case. He read the record aloud, discussed it with those present, and then committed himself as to what he thought had probably been found at autopsy. All those present expressed their opinion, and finally the pathologist demonstrated what had actually been found at autopsy. Dr. Cabot handed to each physician present at the New Jersey Society's meeting a diagram showing the percentage of successes and failures in the diagnosis of certain typical conditions contained in the three thousand autopsies. He stated that the pitfalls came at the end, and the safe ground at the beginning. The percentages were as follows: Diabetes mellitus, 95 per cent.; typhoid, 92 per cent.; aortic regurgitation, 84 per cent.; cancer of colon, 74 per cent.; lobar pneumonia, 74 per cent.; chronic glonerulonephritis, 74 per cent.; cerebral tumor, 72 4-5 per cent.; tuberculous meningitis, 72 per cent.; gastric cancer, 72 per cent.; mitral stenosis, 69 per cent.; brain hemorrhage, 67 per cent.; septic meningitis, 64 per cent.; aortic stenosis, 61 per cent.; phthisis, active, 59 per cent.; miliary tuberculosis, 52 per cent.; chronic intestinal nephritis, 50 per cent.; thoracic aneurysm, 50 per cent.; hepatic cirrhosis, 39 per cent.; acute endocarditis, 39 per cent.; peptic ulcer, 36 per cent.; suppurative nephritis, 35 per cent.; renal tuberculosis, 33 1-3 per cent.; bronchopneumonia, 33 per cent.; vertebral tuberculosis, 23 per cent.; chronic myocarditis, 22 per cent.; hepatic abscess, 20 per cent.; acute pericarditis, 20 per cent.; acute nephritis, 16 per cent ; Dr. Cabot advocated blood pressure examinations as being of the greatest value of any of the methods of diagnosis.

Annual Address by the President.—Dr. Daniel Strock of Camden delivered an address and said that he felt the President of that society should be selected without having necessarily served as Vice-President, though nothing should be considered as preventing the Vice-President to the Presidency. He also advocated the creation of the office of Assistant Secretary.

Moving Picture Illustrations of Nervous Diseases.—Dr. T. H. Weisenburg of Philadelphia presented a series of very interesting moving pictures, which represented the first systematic attempt ever made to show by moving pictures, not only the gait, reflexes, and tremors common to nervous diseases, but also examples of the diseases themselves. Dr. Weisenburg advocated the method for teaching diseases of the nervous system, and for scientific investigations, asserting that many of the fleeting symptoms which could not be detected by the eye were fully illustrated by such photographs.

Embryological and Antenatal Faults as the Cause of Certain Tumors.—Dr. Harrison S. Martland of Newark said that the occurrence of mixed tumors in various parts of the body was much more frequent than most internists believed. He felt that embryology was of great importance in explaining the formation of tumors, cysts, and anomalies. His study had been based on specimens examined at the City Hospital in Newark. He showed some lantern slides illustrating his experiments.

Colored Microphotographs Showing Some Abnormal Conditions of the Cortex.—Dr. Henry A. Cotton of Trenton showed some colored plates which were made by the Lumière process, and stated that they were the first of that kind shown in the United States. He said they had been made in the Trenton Laboratory by Dr. Hammond. The price at the present time was such that the colored pictures would not be used generally, though it was likely that they would be reduced later.

The Relation of the Physician to the Philanthropic and Sociological Work of the Community in Child Life.—Dr. Henry L. Coit of Newark said that the physician's relation to poverty and crime was fundamental and that he should be the logical leader and director in most of the sociological work of a community, as he was better fitted by experience and education to handle constructive and philanthropic problems.

Dr. Alexander Marcy, Jr., of Riverton was of the opinion that no one person in a community gave of his time, his energy, or of his substance, as did the physician to every phase of philanthropic and sociological work. Dr. Marcy believed that the medical profession should be the leaders of thought and action, never followers; and that some restrictions should be placed on the kind of men and women who were allowed to enter that profession, so that those graduating from the medical colleges would be of the caliber to take their proper place in the philanthropic and sociological life of a community.

The State's Responsibility for Its School Children.—Dr. William G. Schauffler of Lakewood stated that New Jersey stood foremost in its care for children of school age, that it led in its wise laws providing for their education and their physical care and well-being. He praised the Medical Inspection Law, which was passed three years ago, and said that it was worthy of being a model for the entire English-speaking world. Dr. Schauffler told of how the educational affairs of New Jersey were cared for, and mentioned several problems of interest to medical men that were engaging the attention of the school authorities at the present time, *i.e.* the compulsory establishment of special classes for backward children, and some very creditable changes in the present building code. Inasmuch as these two improvements were meeting with opposition on the part of the public, Dr. Schauffler suggested that the members of the society should lend their influence to make clear to their communities the importance and necessity of these provisions of the law.

The Relation of the Municipality to the Child.—Dr. Andres F. McBride of Paterson thought that children were entitled to the fullest opportunity for personal development, which included moral, mental, and physical development. Moral development was considered to be largely within the province of the parents, the mental development was a great obligation placed upon the municipality, while the physical development was also a matter of public concern, he said; and most cities recognized the duty resting upon them and were taking up the problems and meeting them with the latest municipal conceptions.

Dr. Francis H. Todd of Paterson thought that the laws brought out by the State Tenement House Commission would, in time, do a great deal to prevent the mortality in young children; and that the Compulsory Education Law, which compelled the attendance at school of pupils until they were sixteen, would do much toward allowing a proper physical development of the child before he was put out to work. That the State of New Jersey was attending splendidly to her responsibilities to the child, was the opinion of Dr. Todd.

Dr. J. Finley Bell of Englewood very strongly advocated the exclusive use of the Metric System of weights and measures for our public schools, claiming that eight months' time out of the school life of a child, which were put in on figures, would thus be saved. He told how in France and Germany, where the Metric System was taught exclusively, the pupils took up the study of algebra one year earlier than in England and America, where the students' minds were befogged by many different tables

Educational Hygiene and Prophylaxis.—Dr. George J. Holmes of Newark said that the duties of medical inspectors of schools ten years ago consisted of inspecting the children to discover whether they had any contagious diseases. He felt that medical inspection of school pupils today was passing through an evolutionary stage; and that while it had many faults and weaknesses, yet many improvements had been made, chief among which, was the backing up of the doctor's efforts by trained nurses, engaged by boards of education for that purpose. He deplored the lack of cooperation on the part of the medical profession at large with the medical inspectors.

The Object and Intent of Medical Inspection of School Children.—Dr. Joseph MacDonald, Jr., of East Orange gave as the basic reasons for medical school inspection the following: The school is the only Governmental department that directly assumes control over children's lives, and nine out of every ten American children are subject to that control during the critical years between seven and fourteen. He said that the object of the Medical Inspection Law could be accomplished by the appointment of a State Medical Inspector, as a member of the State Board of Education; by the preparation of uniform blanks, covering individual record cards for yearly examinations, cards for treatment and exclusion, and cards for infectious or communicable diseases, and by having reports sent by the School Inspectors to

the school boards that they were serving, and to the State Board at Trenton also.

Dr. Edward A Ayers of Branchville spoke on Dr. Holmes' and Dr. MacDonald's papers, and said that one thing badly needed was a crystallization of the whole subject of uniform State laws, for the adjustment, for co-operation, and for standardization. He mentioned the fact that very few boards employed medical inspectors for the schools until it was made compulsory, and that even now they did it on the most parsimonious system possible, calling for contract bids, and awarding the contract to the lowest bidder. He thought a State Medical Superintendent of Inspectors was needed, one whose business it would be to see that the best results possible were being obtained throughout the State. Such a man would have a great work to do, and it would require a physician who was broadly educated. What was wanted was the most efficiency with the least cost, he said; and the public must be brought to realize that funds were necessary for these purposes.

Dr. Charles A. Rosenwasser of Newark stated that in the city of Newark the salaries of the medical inspectors had been reduced, while at the same time additional work had been given them. He asked who was to tell the doctors what they should do. He told of how, in New York City, nurses had been tried out to do the work of the doctors, but without success, and advanced as the solution of the problem that a man be paid a living wage, and asked to devote his whole time to the work. It was his idea that an inspector should not be allowed to send school children to his especial friends for treatment.

Dr. Gordan K. Dickinson of Jersey City mentioned two things which held the Board of Health from appointing a State Inspector; one was the cost, and the other the people. On the one hand was lack of money, and on the other politics.

Dr. D. C. English of New Brunswick declared that outside the cities medical inspection was a farce, and that there should be a head for the entire work.

Dr. Thomas A. Gray of Paterson stated that he was a medical inspector, that he had associated with him six other medical inspectors, and that they all referred every case to the family physician and never treated or advised about the treatment. He felt that the school nurse was a necessity and improved the inspection 100 per cent. Dr. Gray approved of forming an association of School Medical Inspectors of the State in order that all might study the subject together.

Dr. William G. Schauffler of Lakewood felt that the medical inspectors were poorly paid, because of the wishes of the voters, and on account of their not realizing the importance of such work. It was his opinion that country or rural inspection was much better than many thought, and that although it was done under adverse conditions yet in most instances good work was the result.

Dr. Carl E. Sutphen of Newark entered a severe protest against establishing a new clinic run by medical inspectors of schools for the care of school children, and said that the amount of time a child would lose in going to a public clinic was a mere trifle.

Dr. E. S. Sherman of Newark told how he had outlined the work in Newark, and said that while the salary of the medical inspector had been cut down at one time, it had been put back again. He stated that of necessity work of any character would grow, whether the salary grew or not. It was his idea that no professional man could hold the position of school inspector for long; for after a time his private work would become so great that he would have to choose between it and the school work, and since boards of education could never afford to pay a sufficient sum to warrant medical inspectors ignoring private practice, there would be more or less changing. He said that Newark had the best of the younger doctors doing excellent work for a mere pittance; that if they were paid many times the amount, he doubted whether better work would be had, and that the department would be greatly handicapped without the assistance of the school nurses.

The Importance of the Care of the Eye, Ear, Nose, and Throat in School Children.—Dr. Joseph Tomlinson of Bridgeton said that the general medical profession had been rather slow in recognizing the important rôle played by the eye and nasopharynx in producing local and also remote symptoms, and that when it was understood that diseases and defects of those organs rendered the child less capable of performing the tasks imposed, they assumed a special importance. He felt that if diseases of these organs were not eradicated during school life, they would, in many instances, have done irreparable injury by the time adult life was reached. The conditions and environment of school life afforded an opportunity for systematic investigation of these troubles, and also furnished an opportunity for their rational treatment.

Dr. Walter B. Johnston of Paterson advised uniformity in the methods pursued by the different medical inspectors of each community, and felt that there should be no shifting of the work to the shoulders of the visiting or other nurses. He maintained that the inspection of the child as to its physical condition was the business of the doctor, and that nurses should not be allowed to treat a disease, no matter how easy it might be. Young men who were ambitious and anxious to do the work should, he thought, be selected for it; and no inspector—unless he should happen to have been the family physician before he became inspector—should take the case of a child in the school.

Dr. Norton L. Wilson of Elizabeth expressed it as his opinion that nurses were as capable of examining the children's eyes and throats as the doctor, and quite as competent to say that a child should consult a physician as a doctor should be.

Dr. Linn Emerson of Orange said that the medical inspection of the Orange schools was conducted by a woman physician; that the results had been excellent, and that she was earning several times the amount she received. He believed that the public did not realize that the few hundred dollars expended for medical inspection saved them thousands of dollars, and that they should be made to understand that they were getting many times their money's worth. Dr. Emerson favored the inspectors being paid a sufficient salary to warrant their giving their entire time to the work, and thought that this would eventually come. He deplored the feeling of animosity which had grown up between the inspector and the general practitioner.

Dr. Wells P. Eagleton of Newark told of having lived in Newark before the time of medical inspectors, and said that not until nurses were appointed—finding out the details of the cases and following the patients to their homes—was the work properly attended to.

Dr. E. S. Sherman of Newark did not approve of the term "Inspection," as applied to the work, but thought that it should be called medical supervision. He asserted that there would be no cures, no matter how many physicians were employed, unless there were nurses to follow the cases up. He favored free school clinics as a saving of the time of the children.

Dr. Henry H. Davis, Camden, felt that the work would never be a success until there was cooperation on the part of the general practitioners of medicine, and that nurses should be a part of the system of medical inspection.

Skin Affections of Childhood.—Dr. Henry J. F. Wallhauser of Newark said that the skin dunring childhood presented many interesting studies. Some of its diseases were congenital deformities in the histological structure, inherited predisposition, conditions of a perverted functional character, diseases of direct transmission *in utero*, and acute inflammatory and infectious diseases. Under conditions due to the more sensitive nature of the skin during infancy, he grouped inflammations due to mechanical irritations, such as occur from improper clothing, strong soaps, irritating discharges, heat, sunlight, etc.

Some Differences in the Surgery of Children and Adults.—Dr. E. W. Hedges of Plainfield stated that surgery was one of the many agencies for the betterment of child life. He said appendicitis was harder to recognize in children than in adults, and that there was need of earlier operation for that disease in them, because of the swelling of the omentum. There was danger of infection of the Fallopian tubes in young girls, he thought; and in hernia there was a tendency to spontaneous cure in young children. For excessive intraabdominal pressure, he advised treatment by stopping coughs, relieving flatulence, preventing straining at stool or urination, and keeping the patient on his back, with the foot of the bed raised 20°, for six weeks. It was his opinion that operations should be done only in strangulated or irreducible cases, or when the opening was unduly relaxed. He said there was often a tendency to fracture in rachitic children, and that the differences between the structure of the bones of children and of adults was responsible for the lesser tendency to fracture in the young, and to quicker repair. He stated that tuberculous glands were more common in children than in adults.

The Administration of Anesthetics to Children.—Dr. George E. Tuers of Paterson stated that but two anesthetics should be considered—chloroform and ether; and that the least dangerous drug should be administered in the least dangerous way. Chloroform, while the pleasanter, was the more dangerous, though it was indicated in lung, kidney, and brain surgery. Dr. Tuers felt that ether

might be used exclusively in all operations on children, without increasing the death-rate, and he advocated the drop method with a simple inhaler, the operation being done in the early morning, preferably. Care should be taken to prevent the child becoming frightened. He suggested that one begin by giving one drop to three respirations, and gradually increase to one drop to two inspirations, until complete narcosis had been accomplished, then return to the border line. He stated that there was no definite proportion between anesthetic and air, and that great care should be used to keep the patient completely narcotized during the entire operation.

Dr. F. W. Pinneo of Newark asked why a child should be refused an easy induction, because he succumbed readily to a narcotic. He felt that chloroform should be condemned, generally, and that ether should be used entirely, as it was the best means of inducing anesthesia. He spoke of the recent advance in laboratory experiments by Henderson, who had shown the importance of acapnia and of carbon dioxide in the blood as a stimulant to respiration, and said that we had formerly deprived the patient of this, many of the deaths being due to that fact. He emphasized the importance of giving the anesthetic evenly, and not allowing the depth of the anesthesia to vary during the operation.

Dr. Samuel A. Cosgrove of Jersey City observed that whether the toxicity of chloroform was lessened by warming the vapor must remain for a wider use of the method to determine. The important point was that the actual amount absorbed should be constant, and the amounts of the narcotic agent used out of the can had merely an economic, but no physiological importance.

Dr. Philip Marvel of Atlantic City said that there was no such thing as traumatic pneumonia resulting from the irritation of the anesthetic. He asserted that all were proud of the tendency toward having specialists administer the anesthetic, and declared that there had been more serious results caused by drowning the patient through the carelessness of the person giving the anesthetic, whose mind was on what the surgeon was doing, than by any other causes. He advocated the employment of women for that work, those who did not expect to become operators, and whose minds would not be occupied by what the surgeon was doing.

Dr. F. D. Gray of Jersey City mentioned a matter of detail that was new in this connection. It was the combining of essence of orange with ether, in order to mask the odor of the ether and to make it more agreeable to children.

Dr. E. W. Hedges of Plainfield felt that it would take a very long time to induce anesthesia by Dr. Tuers' plan, and said he had never seen a patient got under ether with so small an amount. He told of having given two ounces of sweet oil after every etherization, before the patient had entirely come out, and as soon as they were able to swallow. It had prevented vomiting in almost every instance.

Dr. Tuers stated that he administered the anesthetic one drop to every two or three respirations, in the beginning, because the patient's respirations were rapid, but that as the stage of excitement increased, he increased the anesthetic until he had complete narcosis, and then reduced it to the border line.

Importance of the Care of Children's Teeth.—Dr. J. E. Duffield, DD.S., of Camden gave as the great essentials to health, simple food, fresh air, and exercise, and he placed food as of the greatest importance, and emphasized the fact that plenty of time should be spent in chewing it before it was carried to the stomach. He said that it was very important that people should have clean, sterile teeth, for if foods were infected during the process of mastication they would be absorbed in that condition, and ultimately result in disease. Ninety-six per cent. of school children had decayed teeth, he asserted. The teeth should be brushed at least twice a day, and examined by a dentist at least once a year. He felt that by systematic examinations all serious dental troubles could be avoided.

Dr. William G. Schauffler of Lakewood thought that free dental clinics had done much to help along the cause of conservation in children, and that there could be no question as to their necessity.

Dr. Alexander Marcy, Jr., of Riverton said that if we would have a child do his best, both in and out of school, it was necessary to see to it that he was not handicapped by any removable physical defect, and particularly to see that he had a good set of teeth. He emphasized that it was not only for the good of the teeth themselves that such care was advocated, but that the general well-being of the child depended upon it.

Dr. R. C. Newton of Montclair complained that little children were not made to chew, and that that was the cause of bad teeth. He said if the lower jaw was used, the upper teeth were driven out first and the upper jaw would be spread. On the mandible depended the shape of the upper teeth.

Dr. Alexander McAlister of Camden said that parents were often indifferent to their children's teeth unless they had toothache. Many mouths got into a terrible state, with but little or no complaint on the part of the children. It was his opinion that many pupils stood at the foot of their class because of neglected mouths. Bad teeth caused bolting of food, with infection from many pathogenic bacteria, thereby producing indigestion and intestinal toxemia, which resulted in faulty metabolism and imperfect development in the child.

Dr. Duffield declared that there was no question but that the examination of school children's teeth and the work of the free dental clinic went hand in hand, and were going to accomplish, in the very near future, a great work.

The Evolution of Abdominal Surgery, with Recommendations as to Technique.—Dr. Frank D. Gray of Jersey City read a paper which dealt in a comprehensive manner with the status of abdominal surgery—past and present—covering features of progress in operative procedures of both the upper and lower zones. A forecast was also made as to some probable directions in which improvement of already remarkable achievements might yet be effected. Especial emphasis was laid, too, on certain evolutionary forces, which even though often disregarded as commonplace and obvious, because of their every day application, had yet been most potential and far reaching in practical results. Finally a strong plea was made for a more general employment of the "Maunsell" method of intestinal anastomosis modified by using it in connection with the "Connell" suture—two methods of technique which the writer believed worthy of much more general use than had so far been accorded them, and which he regarded as superior to the usual all-suture plan or any of the various methods that required the use of mechanical devices.

Blood Pressure.—Dr. J. D. Lippincott of Newark made a plea for the more general use of the sphygmomanometer, particularly in diagnosis, prognosis, and the treatment of arteriosclerosis, acute and chronic nephritis, and the toxemias of pregnancy. The routine use of the instrument he had found of inestimable value in his practice. In no other way had he been able to judge the degree of hypertension so accurately. He felt that the blood-pressure readings alone were worth more than any other symptom as a diagnostic aid. The writer had found that a blood pressure in pregnant women of from 125 to 150 mm. needed careful watching and moderate elimination treatment. A pressure of over 150 mm. required unusually active elimination treatment and diet and might require the induction of labor. He recommended the taking of the blood pressure every two weeks in order to save such women from the more prodromal symptoms of toxemia.

Dr. T. N. Gray of East Orange was of the opinion that all arteriosclerotics were, sooner or later, nephritics. In high blood pressure he had found the same degree of symptoms that he had got from the enlargement of the heart, and thought there must be a compensatory relation. One patient with 212 mm. did not have anything like the symptoms of the one with 194 mm. The basal diagnosis should be influenced by the general condition of the patient in connection with the reading of the instrument.

Dr. Francis R. Haussling of Newark praised the sphygmomanometer as an aid to diagnosis, because of its ease of application, its accuracy, and its reasonableness of price. Dr. Haussling had collected 682 readings on 140 pregnant women in apparent good health. In the series the lowest systolic reading was 80 mm., the highest, 150 mm., the average was a trifle over 113 mm. With or without symptoms, in a blood-pressure of 150 mm., active treatment should be given.

Dr. James G. Prendergast of Philadelphia said that in 85 per cent. of the cases in which hemorrhages had occurred after opening the eye, the blood-pressure had shown that arteriosclerosis and nephritis were back of them. Arteriosclerosis always began with toxemia, he said; but what the toxic substance was, no one knew. He recommended that every man, after reaching the age of forty, have a blood-pressure examination made every year from that time on.

Dr. L. F. Bishop of New York City stated that nine-tenths of all cases of arteriosclerosis were due to amino-acid poisoning, or so-called autointoxicative conditions, when one left out of account the high blood-pressure cases due to pregnancy, those due to nephritis of toxic origin, and those due to arteriosclerosis following syphilis.

He believed that arteriosclerosis was the result of the individual damage to the heart, blood, and kidneys from some particular protein amino-acid, which was characteristic of the individual. He considered the use of salines harmful in arteriosclerosis and high blood pressure, as they increased intestinal intoxication. He used castor oil in all his cases of amino-acid poisoning, but said that the best and safest antidote for high blood-pressure was outdoor exercise. He did not believe in the use of nitrites to reduce blood-pressure.

Dr. C. A. Rosenwasser of Newark declared that every man should have a sphygmomanometer; but gave a way of telling the approximate blood-pressure without one. As the normal pulse should be 72 sitting up, and six or eight degrees lower when lying down, if it did not drop when the patient lay down one could be sure something was wrong. If it went up materially there would be high blood-pressure, and if the cause was hard to find he suggested looking for tuberculosis.

Indurative Headache.—Dr. Christopher C. Beling of Newark had studied that particular type of headache for the past five years. He gave heredity as an important predisposing cause, with exposure to cold, damp, and wet, as common exciting causes, while sudden changes in temperature, local injury or strain, and the presence in the circulation of toxins, were also important factors. Treatment should be first with massage, and then with the sinusoidal current. He advised that all physicians, when called upon to treat headaches, look for the presence of an indurative condition before administering sedative drugs, which would, in such a case, only temporarily ameliorate the symptoms.

Dr. William M. Leszynsky of New York City explained that the condition occurred very often in a large mass of fibrous tissue that came forward to the forehead. He said that such patients not only had hypertonias or some rigidity, but also some other evidences of rheumatic diathesis, or some history of some form of toxemia. He considered the use of the sinusoidal current a more rapid method of treatment.

Dr. Sarah R. Mead of Newark mentioned that her patients had received benefit from massage treatment first. Later she had used the vibratory method, and care by internal medicine.

Dr. Beling said he had found the sinusoidal current the best physical exercise there was, because it would grasp the muscle, stimulating it, and would get down deeper to the tissues. That treatment should be combined with massage.

Ivory Exostosis of the Skull.—Dr. Richard C. Newton of Montclair stated that ivory exostoses arose from membrane bone and were particularly prone to grow from the walls of the orbit and skull. They were slow-growing, usually sessile, hard, and painless. The symptoms in children were usually persistent headache in the frontal region, sanguineous and purulent discharges from nostrils, and the formation of symmetrical swellings, the size of an almond, in the region of the nasal process of the superior maxillary bone. The only treatment was operation in Dr. Newton's opinion. He praised the *x*-ray for use in confirming the diagnosis.

Dr. F. D. Gray of Jersey City thought that unless the growths were producing serious symptoms they should be left alone, because operation was dangerous, and sometimes fractured the skull, though the modern use of the electric burr and saw had made operation more practicable than formerly.

Dr. Thomas W. Harvey of Orange expressed the idea that ivory exostosis might be caused through a loss of the inhibition of the production of building material. Such inhibition usually resulted in the growth of bony tumors, and might be found to be due to disease in the pituitary, adrenal, thyroid, etc.

Opportunities.—Dr. Wm. A. Westcott of Berlin, N. J., spoke of how widely the medical profession differed from all others. He said there was no such thing as co-operation among doctors. Their task was always serious and often terrible; yet no work in life spoke so little for itself as the medical. The very nature of the calling made a doctor's interests secondary to the needs of others. Dr. Westcott deplored the fact that the State bound physicians to maintain rules for sanitation, but permitted competition against them, greater than that against any other class of men, as evidenced by the fact that 1,100 drug stores in New Jersey were doing an irregular business (selling patent medicines) amounting to $13,325 a day. He gave as a remedy for this danger to the work of the physician and the general health of the citizens, better organization on the part of the doctors, without regard to party lines, and the establishment of a standard for the sale of patent medicine (which is the practice of medicine) that would conform to the same high standard as was required of the physician.

Public Conservation of Human Lives.—Dr. Harry W. Kice of Wharton stated that it was the duty of every citizen, who was acquainted with the facts bearing on the subject of the conservation of human lives to see that the Government became interested in that question also. He declared that the medical profession should create a public sentiment that would demand of the Government the adoption of such measures as would best conserve the lives of its people. He said we needed protection from disease more than from invading armies, and that our infant children needed protection more than our infant industries.

The Alcohol Inebriate: What Can We Do for Him Under Existing Conditions in New Jersey?—Dr. C. A. Rosenwasser of Newark gave a series of five groups or classes of inebriates and the treatment for each group. Group one included persons who were daily consuming a small amount of alcohol while attending to their duties. The remedy at this stage was for the individual to let alcohol in every form alone. Group two comprised persons who had gradually developed from what is generally called moderate drinkers to heavy drinkers. The remedy was plain, but difficult to apply, because the patient did not realize that he was doing himself an injury; but he should place himself under the charge of a reputable physician for treatment. Group three was composed of inebriates, subject to periodical sprees, and who between the attacks were usually sober citizens. Restraint in an institution was often required for these. Group four consisted of inebriates who had become unable to manage their own affairs, and who were a menace to society. They should be placed under restraint, for their own protection as well as for that of others. Group five was made up of inebriates who failed to provide for their families, beat their wives and otherwise violated the law. They should be examined by a physician, and, if mentally defective, sent to an asylum; or, if not irresponsible, they should be sent to jail. Dr. Rosenwasser declared that no victim of the drink habit could be cured against his will, and that there was nothing that could be given him secretly that would cure him. The results of the treatment of the drink habit were as follows: Some patients were cured; some were improved; and some were incurable. For the inebriate who wished to remain sober there was but one road, the writer said, and that was total abstinence. The drink habit was like other chronic diseases, prone to relapse, and such relapses called for treatment, not condemnation. He stated that in several States—of which New Jersey was not one—there were hospitals and farm colonies for the treatment of inebriates.

Dr. Alexander Marcy, Jr., of Riverton was strongly of the opinion that the State should provide an institution for the study and care of that class of cases. He felt many could be cured and that such an institution could be made, in time, self-supporting. He suggested that the liquor interests should be taxed to support institutions which it made necessary.

Dr. E. B. Rogers of Collingswood favored prevention as the cure for inebriates. He did not believe in classing them as insane, and said that the State should provide private wards in the insane hospitals for inebriates, inasmuch as it admitted them to such institutions as private patients. He objected to the State's taking their money and then putting them in with the insane people.

Dr. Norton L. Wilson of Elizabeth related having once known a man who scorned the idea of entering an ordinary saloon, but who intoxicated himself every week on two bottles of bitters.

Premature Arterial Senility.—Dr. W. Blair Stewart of Atlantic City said that various irritants increased the activity of the heart and blood-vessels and would have to be eliminated by the kidneys, skin, and liver. Every increase in rate and pressure upon the vessels caused a hypertrophy of the heart, followed by hypertrophy of the muscular arterial coats. In time these coats would give way to degeneration and deposits of calcareous matter, and atheroma would be produced. He recommended the careful watching of the blood-pressure, and said that in early cases the removal of the cause would suffice. He stated that many patients with atheroma lived for years with little or no discomfort, provided rational methods were exercised. It was his belief that if the physicians could regulate dietetics and exercise, and break up the sedentary, lazy habits of their patients, there would be less atheroma, greater longevity, and increased happiness.

Dr. L. F. Bishop of New York City suggested that a distinction be made between atheroma and arteriosclerosis, the former being a senile hardening of the arteries, and the latter a compensatory process.

The Absolute Prevention of Lockjaw.—Dr. Dowling Benjamin of Camden presented a paper which dealt with prevention as the only satisfactory cure for lockjaw, giving as the mortality after the disease had developed, 95 per cent. A description of the method of prevention was gone into by Dr. Benjamin, and was as follows: One should have on hand a set of six screws, of different sizes (prepared by an instrument maker if possible), ranging from the size of a small probe to 5/16 of an inch in diameter, and about 3 inches long. The field of injury should be sterilized, and large open wounds irrigated. Insert a few drops of alcohol solution of cocaine. Dip the screw, which should be the size to follow the track of the wound, into an antiseptic solution; insert in the wound, and keep turning, holding back somewhat, so that by the time it has reached the bottom it will have been turned enough to have carried it more than twice as far. Give it a few more turns so as to lift or screw out the foreign substances or microbes. Remove the instrument; wash in antiseptic solution; dip in iodine; force down to the bottom of the wound again; give a few turns backward; remove the screw; dip into carbolized oil, and push gradually to the bottom of the wound, turning backward, and then unscrewing out. Dress the wound in the usual antiseptic manner. No germs will live in the wound.

The following officers were elected for the ensuing year: *President*, Norton L. Wilson, Elizabeth; *First Vice-President*, Enoch Holingshead, Pemberton; *Second Vice-President*, F. D Gray, Jersey City; *Third Vice-President*, N. J. Chandler, South Orange; *Recording Secretary*, T. N. Gray, East Orange; *Corresponding Secretary*, H. A. Stout, Wenonah; *Treasurer*, Archibald Mercer, Newark.

The next meeting will take place at Spring Lake, N. J., on June 17 to 19, 1913.

BRITISH MEDICAL ASSOCIATION.

Annual Meeting, Held in Liverpool, July 23-26, 1912.

(*Concluded from page 313.*)

SECTION ON SURGERY.

Third Day—Friday, July 26.

The Treatment of Gastric Ulcer by Excision and Partial Gastrectomy.—Dr. J. F. Dobson of Leeds read a paper on this subject, of which the following is an abstract:

Operation of gastroenterostomy was most satisfactory, he said, for the majority of cases of chronic ulceration of the stomach and duodenum. There was a small residue of cases for which the operation was not of such value. These were mostly examples of ulceration of the lesser curvature or of the body of the stomach. The author had practised excision in some of these cases, and the results were such that publication was desirable. Excision of the ulcer would seem to be the ideal procedure, for by this the lesion was cleanly removed; the possibility of secondary malignant disease was avoided; no risk of contraction producing stenosis of stomach. Nevertheless the author had seen some deplorable results of excision, and he lately practised a modified form of partial gastrectomy on two patients, both of whom made satisfactory recoveries. The advantages of the modified partial gastrectomy were: Clean excision of ulcerated area of stomach; no possibility of malignant disease in ulcer or of perforation or contraction; it was easier than wedge-shaped excision of stomach. But there was some risk of jejunal ulcer and it was a much more formidable operation than a simple gastroenterostomy.

Mr. Wheeler of Dublin thought gastrectomy was too severe an operation for the treatment of gastric ulcer; in view of the rate of immediate mortality it was unacceptable as an alternative to gastroenterostomy. When the posterior wall of the stomach was fixed by firm adhesions, a surgeon was not justified in distributing the parts to the extent necessary for partial resection.

Mr. Hey Groves of Bristol contrasted the high mortality of 15 to 20 per cent. after gastrectomy with the much lower rate of 5 per cent. incident to gastroenterostomy. He thought it best to operate in two stages—first anastomosing the stomach and jejunum; and then, after an interval excising the ulcer, if that step is indicated by the symptoms. The second stage was thus rendered both safer and easier, because of the improved nutrition of the patient and the lessened inflammation in the region of the ulcer.

Surgery of the Sacroiliac Joint.—Mr. W. J. de C. Wheeler of Dublin said the diagnosis of sacroiliac disease was difficult and uncertain in the early stage, the treatment as a rule unsatisfactory and often unscientific and the prognosis was bad. Very feeble attempts had been made to recognize and treat this disease in the early stage notwithstanding the fact that after suppuration had been established it was extremely fatal. The textbook signs and symptoms appeared when there was extensive destruction of the joint and presented an unmistakable picture, but at a time when surgical treatment was generally futile. Sciatica was often the earliest symptom, and this was not to be wondered at, seeing the intimate relation of the lumbosacral cord to the anterior part of the joint. The skiagraphs gave clear and valuable information and should always be resorted to in cases with sciatica or vague lumbosacral pains which resisted ordinary treatment. The joint was not inaccessible and its anatomical relations were most encouraging from an operative point of view. The joint should not be approached from behind, the posterior sacroiliac ligaments offered a barrier which if broken down interfered immeasurably with the suspension of the sacrum and superimposed trunk on the iliac bones. Injury to these structures could be repaired only after bony ankylosis which required prolonged rest. The attachment of the gluteus maximus and the very powerful formation of bone in this region also made the posterior an unfavorable route for approach to the joint. A trephine or gouge or burr applied in the middle of the fossa occupied by the gluteus medius muscle midway between the crest of the ilium and the sciatic notch would reach the upper and anterior part of the joint without difficulty. The position of the incision below the junction of the anterior two-thirds with the posterior two-thirds of the crest of the ilium was an admirable one, lying as it did between two sets of blood vessels, the segmental above and those for the limb below. The author's conclusions were as follows: "(1) The disease once well established is a very fatal one. (2) Radical treatment in the early stage offers a good chance of recovery. (3) The signs and symptoms usually described do not exist in the stages of the disease in which treatment promise most. (4) Vague and persistent pains in the lumbosacral region especially when referred down the sciatic nerve should arouse suspicions of sacroiliac disease no matter what the age of the patient. (5) An *x*-ray photo is a valuable aid. (6) Early operation to remove the focus of the disease is indicated in this joint as in others; the joint is not inaccessible and is easily reached with the least possible anatomical disturbance."

Successful Ligature of the First Part of the Left Subluvian Artery in a Woman.—Dr. Newbolt of Liverpool related the case of a middle-aged woman on whom he had performed this operation for aneurysm, and showed the patient in good health. There were various lesions in the cornea and elsewhere which indicated syphilis, but iodides in the form of KI and NaI quickly produced a rash and could not be tolerated. The artery was reached by resecting a piece of the sternal end of the clavicle, for which purpose a Gigli saw was used. Two silk ligatures were applied half an inch apart, and merely drawn tightly enough to occlude the vessel. The wound was closed without drainage, and complete cure of the aneurism resulted. The author thought silk twist preferable to catgut or kangaroo tendon for ligating a large artery.

Prof. Rushton Parker, president of the Section, referred to Lister's success with catgut ligatures.

Mr. Fullerton of Belfast and Mr. C. H. Fagge of London said they had found catgut quite satisfactory for tying large arteries in continuity.

One Thousand Cases of Total Enucleation of the Enlarged Prostate.—Mr. P. J. Freyer of London set out in this paper his experience of prostotectomy since the date of his first paper eleven years ago. The average age of his patients was 69, and the extremes 49 and 90. The weight of the gland removed varied between ½ ounce and 17 ounces. He has succeeded in reducing the mortality from 10 per cent. in the first 100 cases to 3 per cent. in the last 100. In nearly all the fatal cases the kidneys were seriously diseased as a consequence of many years' obstruction. Vesical calculus, mostly phosphatic, was present in 180 cases, and the mortality of such patients was higher than the average. He operated by the suprapubic route, a rapid enucleation occupying only two minutes sufficing when the enlargement was mainly glandulous, while a tough fibrous prostate might require nearly one-half an hour. Why the organ enlarged and what were its necessary functions were questions to which he was not prepared to give an adequate answer. His patients were derived from all social and physical types, and from many nationalities; and the usual results were complete control

over the bladder and the restoration or maintenance of sexual power, together with remarkable recovery of health. So marked an improvement, amounting to rejuvenescence suggested the theory that an enlarged prostate is the source of a malign internal secretion.

Mr. C. A. Morton of Bristol asked the author if it was his practice to enucleate the cancerous prostate; and if so what had been the ultimate result.

Mr. Fullerton of Belfast spoke of the great difficulty encountered in removing a fibrous gland, as contrasted with the easy enucleation of the adenoid variety. He had met with patients in whom the symptoms began soon after 40 years of age. His personal experience extended to 55 cases of prostotectomy with four deaths.

Mr. Ballance of Norwich pointed out the advantage of operating in two stages when pyelitis was a complication. He had lost cases owing to infection of the area of raw tissue caused by enucleation, and he thought a perineal drain would be of service.

Mr. Hey Groves of Bristol said the average results of prostotectomy obtained by hospital surgeons in general were very disappointing. A few years ago on compiling the statistics of a number of large hospitals he found the recorded mortality to be 40 per cent. So unjustifiable a death rate demanded a stricter selection of cases and a more frequent resort to preliminary drainage of the bladder for some days before removal of the prostate.

Mr. Newbolt of Liverpool commented on the force that had to be exerted in shelling out a hard, fibrous organ; and on the lower mortality in private than in public practice. He invited Mr. Freyer to give details of his operative technic.

Mr. Freyer closed the discussion. He thought Mr. Hey Groves' figures fallacious: last year in St. Peter's Hospital there were 98 cases with only 5 deaths. He agreed that operation in two stages was advisable in some cases. A perineal drain was needless; he used a suprapubic tube 1 inch in diameter, and the bladder was irrigated twice a day. A malignant prostate should never be removed unless it were free and mobile.

A Series of 100 Consecutive Cases of Acute Appendicitis; Immediate and Remote Results.—Mr. H. J. Paterson of London submitted a tabulated summary of his operations for acute appendicitis in the last three years. The number of cases was 95, of whom 90 recovered, leaving a death rate of 5.2 per cent. Every case was operated on as soon as possible after the diagnosis was made. Those who opposed early operation were challenged to show better results from delay. His own settled conviction was that immediate operation is the treatment of choice; and he adopted Murphy's dictum that "there should be no deaths from appendicitis."

Sir George Bealson of Glasgow denied that immediate operation is the best treatment available for many cases when first seen; though he would not apply this assertion to cases coming under observation within a few hours of the onset of appendicitis. There is a large intermediate group divisible into two classes, (a) with general peritonitis already present, and (b) with localized abscess. Cases in class a require prompt appendicectomy and drainage; whereas such treatment is dangerous and disastrous for class b, the right course here being expectomy, and in the meantime the administration of suitable medicines and diet. For 14 years he has followed this course in 273 cases of appendicitis with local abscess, 264 of whom survived the attack and were subsequently cured by appendicectomy with the exception of 8 who refused operation. The diagnostic test of local suppuration is leucocytosis associated with a normal relationship between the temperature and pulse. As to treatment he advised opium in the form of Dover's powder, bismuth, a dietary reduced almost to starvation point, a simple enema every second day, and local poulticing to promote the immigration of leucocytes.

Mr. C. H. Fagge of London said Sir George Bealson's doctrine of delay was pernicious and if acted upon it would inevitably increase the mortality of acute appendicitis. In practice it was impossible to discriminate serious cases from the benign. Exploration constantly revealed conditions that could only be guessed at beforehand.

Mr. H. Stiles of Edinburgh said his experience did not accord with the views of Sir George Bealson. As a means of reducing the mortality he urged the adoption of the following rules: (1) Never give chloroform in these cases; the patient is already toxic and chloroform increases the danger in every form of acute toxemia; ether is the preferable anesthetic. (2) Always remove the diseased appendix; a large wound may be required but there need be no hesitation in opening the peritoneum freely. (3) Wash out the stomach; foul vomit indicated stasis in the small intestine and in this condition repeated lavage of the stomach was of the utmost value. (4) Do not wash out the peritoneum, but rely on adequate provision for drainage.

Prof. Cameron of Toronto also advocated lavage of the stomach. On the question of operation he was in general agreement with Sir George Bealson. Doubtful cases were those seen for the first time on the second or third day of the disease. If he was called in on the fifth day as a rule he advised expectant treatment.

Mr. Paterson closed the discussion. He said time limits in this disease are now out of date, and the modern resources of surgery enable us to operate at any stage. Contrasting the rival methods he pointed to hepatic infection, subphrenic abscess, and septicemia as incidental risks of delay; and reminded the advocates of expectomy that their surviving patients still retained morbid appendixes for future operation; nor could they say positively, on clinical evidence, what were the exact local conditions in any case of acute appendicitis.

The Preoperative Diagnosis of Appendicitis.—Dr. William Ewart of London read a paper on this subject and gave a demonstration of a dorsal method of examination by percussion with the aid of a pleximeter. This method provides normal "standard" physical signs for the healthy state, and abnormal "localizing physical signs" for the retrocecal lesions and for some of the central and of the pelvic lesions, whereas abdominal palpation could reach only the anterior lesions, added considerably to the range of our objective preoperative diagnosis (both positive and negative) by demonstrable physical signs. It was simple and rapid, painless and harmless, and, within its own competence, singularly accurate and reliable. The practical conclusions claimed to have been established by an extensive clinical investigation, and by confirmatory surgical test cases were as follows: "It is the only available test (1) for the normality of appendical district; and (2) for the post-operative results of surgical interference, whether completely successful, or sometimes calling for a secondary operation. (3) It is unique in supplying direct localizing evidence in the large group of retrocecal lesions, which are inaccessible to preoperative diagnosis even by *x*-rays; often also in the pelvic and sometimes in the central lesions. (4) Except in the anterior group of appendicitis, hitherto the only group of physical signs, it is the only objective evidence for deciding at once the urgency of operations which at present are undertaken for existing symptoms; and (in their absence) the expediency of operations now justified by nothing else than the plea of safety. (5) It has a direct bearing in all cases upon the modus operandi: not only in the deep-seated and posterior ones; but particularly in the anterior ones, where it is capable of settling any doubts as to the management of the retrocecal field. (6) It is indispensable for certificates of appendical soundness, and of a perfectly normal result after operation; (7) for the decision as to an operation in all subacute, latent, or doubtful cases; and (8) for the most satisfactory operative management of severe cases. With exceptional reservation a dorsal examination should never be omitted as an essential part of the routine of surgical preoperation diagnosis."

Mr. J. T. J. Morrison of Birmingham expressed the thanks of the Section for the demonstration. He thought Dr. Ewart had proved his thesis, and he welcomed the sacroiliac percussion test as a distinct advance in clinical knowledge, and as an addition to the recognized means of diagnosing the state of the appendix.

Gastric Ulcer: Its Pathology, Diagnosis and Treatment.—Sir B. Dawson spoke of mucous ulcer as a subacute affection which usually healed quickly though occasionally it went on to perforate or in other cases became chronic. This last condition usually involved all the coats of the stomach. Duodenal ulcer is closely related. On the two sides of the pylorus there were the same conditions. Ulcers could be produced by lowered vitality or damage by various agents, by infection, toxic or bacterial. But hydrochloric acid played a part as ulcers were confined to the region where it existed. Experimental damage alone did not lead to ulceration but when combined with acid juice did so. This was important in connection with operative proceedings. But in human beings attacked by ulcer there was almost always bacterial infection. Chronic ulcer suggested irritation of considerable duration. Pathology indicated an origin in the mucous form spreading to the submucous coat but if the case was acute perforation might occur instead of the chronic ulcer of less rapid formation. The speaker

contrasted cases diagnosed as ulcer in preoperative days with those seen on the operating table. In the former a case of perforation or hemorrhage now and then was seen at autopsy and it was thought the others were ulcers which healed by first intention, assisted by treatment. The main diagnostic symptoms were pain, tenderness, and acidity, but motility was sometimes increased which might be shown by *x*-rays. These symptoms as also vomiting and hemorrhage might exist in other conditions. Diet must have the first place in treatment and should be most carefully regulated and assisted by rest in bed. Drug treatment was summarized as directed to meet the hyperacidity, which should be completely neutralized. If this could not be done, and if return to usual diet or to work brought on relapse, operation might be required as it would if stenosis was present. He would not recommend surgical measures until medical treatment had been fairly tried for two months.

Dr. Saundby said there was often no little difficulty in diagnosis and in such cases it was better to presume that there was ulceration and treat accordingly. He agreed that rest in bed was of prime importance and disagreed with the old plan of low diet. For years he had taught that mouth feeding could be carried on in bed throughout. He did not think drugs could do much and the use of *x*-rays must be of little, if any, value.

Dr. Michell Clarke commented on the importance of diagnosis from cancer.

Dr. William Hunter considered staphylococcal and streptococcal infections through the mouth as the cause of the ulcers.

Dr. Vaughan Hanley looked as confidently to a chemical cause. Hyperchlorhydria was constant, and increased when the pylorus was affected by spasm or stenosis. Pepsin was usually present in great excess. He believed in medicine. Bismuth subnitrate was a most valuable remedy and in uncomplicated cases he would not recommend a resort to surgery.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Second Day—Thursday, July 25.

Eclampsia.—Dr. J. W. Ballantyne of Edinburgh opened a joint discussion with the Section of Pathology on Eclampsia. He discussed the etiology and said that it was now generally agreed that pregnancy was the cause of eclampsia, but it was not a normal pregnancy. Eclampsia was more common in primiparæ and with twins, also in cases of illegitimacy. He thought that its occurrence was favored by atmospheric conditions and that it was more prevalent in cold, foggy or warm, muggy weather. It was extraordinarily difficult to state emphatically any single fact in its etiology. It may be regarded as a toxemia; some have supposed that it was of microbic origin, but he was opposed to that view. A characteristic feature was evidence of renal inadequacy shown by diminished excretion, albuminuria and the presence of blood and tube casts in the urine. There could be no question of the importance of albuminuria as a danger signal. There were signs of inadequacy in the liver and great constipation. There was also evidence of inadequacy of the thyroid and parathyroid glands. Some had also incriminated the suprarenal and pituitary glands. He referred to Selheim's mammary theory which had led some to advocate and practice removal of the breasts. The corpus luteum had been looked on as a causative element and others had tried to find the cause in poisons generated in the fetus and placenta. As regarded treatment: at one time he practised active interference and found the mortality 20 per cent. During the last four years he had left the uterus alone and the mortality had fallen to 10 per cent. His treatment included the administration of six ounces magnesium sulphate with sufficient water to dissolve it, by stomach tube. He seldom gave morphine. He used saline infusions, but with chloride of calcium instead of sodium chloride; 30 grains in one pint. Later he gave the same salt by the mouth, 30 grams three times daily. He drew the following conclusions: The chief factors were pregnancy, and renal and hepatic inadequacy. The disease was a pathogenic toxemia and antitoxemic measures in some cases succeeding in arresting the fits without interfering with the pregnancy, the patient subsequently being delivered of a living child.

Dr. Teacher of Glasgow opened the discussion from the point of view of the morbid anatomy. He said that postmortem investigations showed that the most striking changes were in the liver, there being fatty degeneration and cloudy swelling with the presence of hemorrhagic foci. In some cases there was cerebral hemorrhage; there was no relation between the degree of pathological change and the severity of the symptoms. The general opinion was that the symptoms were due to a toxemia resembling uremia on one side and septicemia on the other. The characters of the lesions were due partly to the high clotting power of the blood and to the action of the toxin on the walls of the vessels. There was necrosis around the portal tract, whereas in acute yellow atrophy the necrosis affected the center of the lobules. The changes in the liver cells were shriveling and vacuolation. In the kidney the tubules showed necrosis and this was accompanied by hemorrhage between and into the tubules. A rare lesion which he had found and of which he showed pictures on the screen was symmetrical necrosis around the outer edge of the cortex of the kidney. This necrotic band was marked off from the rest of the kidney by a band of hemorrhage. In the cases in which he had discovered this lesion there had been complete suppression of urine and the fits had ceased, the patients dying after five or six days of suppression.

Sir William Smyly of Dublin said that the treatment was influenced by three considerations: (1) Efforts to prevent the formation of toxins. (2) Neutralizing the results of the toxin. (3) Elimination of the toxins from the system. When obstetricians were influenced by the first consideration they used a forcible rapid means of emptying the uterus. Dührssen recommended rapid emptying of the uterus after the first fit and reported good results. Some considered that the cause lay in the placenta and when fits continued after delivery they advised curetting the uterus. He referred to Tweedy's theory that the intestinal tract was the main source of origin of the poison and his plan of washing out stomach and bowel and withholding all food, including milk, allowing water only. Pinard had stated that he had never seen a case of eclampsia in a patient who had been on prophylactic treatment for 8 days or more. The elimination of the toxin was encouraged by the action of the kidneys, bowels, and skin, though personally he did not believe in diaphoresis. He advocated saline infusion but there was danger from chlorides and he suggested sugar as a substitute. Bleeding was coming into favor again. Lumbar puncture had been tried but had not much support. One of the latest theories was that the disease was due to spasm of the arterioles and on this account chloral was advocated. Symptomatic treatment is considered in guarding the patient from injury—mop out the throat and turn patient on side with head over edge of bed; give oxygen after each fit; if high arterial tension use phlebotomy and veratrum viride. The important point was to determine whether to procure immediate delivery. Vaginal cesarean section was impossible out of hospital. The general practitioner generally used accouchement forcé. In his opinion this was the worst form of treatment possible. The best results so far reported were those of Stroganoff, who, using a non-operative plan, had in 900 cases reported a maternal mortality of 8 per cent. and a fetal mortality of 21 per cent.

Dr. Walker Hall of Bristol said that physiological chemistry showed that there was something in the blood of pregnant women which had the power of splitting up the amino-acids in the early months of gestation. The organism was coping with overwork by overstrain, and if the balance was disturbed then we got eclampsia as one result. He thought that all the present methods of treatment acted by "shocking" the nervous cells into a state of insensibility, from which they recovered without again acquiring their bad habit.

Dr. Leith Murray of Liverpool was entirely against the view that anaphylaxis was a cause of eclampsia. He thought that the changes in the liver were due to the hemoagglutinative action of the corpus luteum secretion. Many cases died of cerebral hemorrhage. The toxin resembled snake venom poison in its effects, but except for that resemblance it was unique. All venom products were obtained from glands and he thought it possible that eclamptic toxin was formed by the syncytial cells of the placenta.

Dr. Haultain of Edinburgh believed that the liver was the main source of the toxin. The disease was very prevalent in Edinburgh, but rare in Dublin, and he believed the Edinburgh prevalence was due to the cold easterly winds of that city. He used blood-letting but not salines. He had given up morphia and chloroform entirely; gave bromide and chloral 60 grams and 30 grains respectively by enema. He believed in emptying the uterus; in most cases one found that labor had already begun; but even in pregnancy he emptied the uterus, using cesarean section if necessary.

Sir John Byers of Belfast believed that the weather

had nothing to do with causation. He had given up diaphoresis and was not in favor of blood-letting. He used saline solution, but advocated the Ringer-Locke solution, which was based on an analysis of the salts in normal blood. He gave morphine freely and was entirely opposed to emptying uterus.

Dr. Scharlieb of London spoke of her experiences in Madras forty years ago, where eclampsia was very prevalent, though the climatic conditions were entirely opposite to those of Edinburgh, and the people ate no meat.

Dr. Sholto Douglas of Birmingham said that experiments showed that, when blood was drawn from an animal, the antibodies remaining in the blood were increased and later fell. He thought this explained the good effect of bleeding rather than the idea that the poison was actually removed from the blood.

Professor Chipman of Montreal, vice-president of the section, said that he was present at a discussion on eclampsia at Baltimore in May and he compared the opinions with those now expressed. The one fact which emerged was the amount still unknown on this subject. The cases might be grouped clinically into: (1) Those in which the liver was most affected; (2) those in which the kidney was most affected. The liver cases were the more severe and had fewer prodromi. In these cases he advised early delivery.

Third Day—Friday, July 26.

Chorio-Angioma of Placenta.—Dr. R. W. Johnstone of Edinburgh read a paper on this subject. He said that his was the seventy-first case of genuine placental tumor, excluding cysts, which had been recorded, but they were probably more common, as all the reported cases were from institutions. In his case there was marked hydramnios. Examination of the tumor showed that it occupied about one-fourth of the total area and was composed of pedunculated lobules, varying in size from a pea to a plum. Each lobule was covered with chorionic epithelium, both layers being recognizable, and being reflected on to the pedicle of each lobule. There was no true capsule to the tumor but a layer of degenerated villi and fibrin which formed a sort of false capsule. The mass of the tumor consisted of capillaries engorged with blood and supported by a delicate connective tissue and he regarded it as a capillary angioma. Most of the previously described cases had been called myxomata.

Rupture of Uterus in a Case of Concealed Accidental Hemorrhage.—Dr. Shannon of Glasgow described a case of this nature. The patient, a 10-para, was seized with acute abdominal pain and syncope. The uterus was found to be hard, tender and larger than normal. Cesarean section with supravaginal hysterectomy was done but patient died of shock. The uterus was found to present multiple ruptures, many involving peritoneal coat only, some extending into muscle, but none invading mucous membrane. He said that in all cases of concealed accidental hemorrhage the uterine wall was diseased and he attributed the ruptures to sudden distention of this wall.

The Excretion of Creatin in Pregnancy and the Toxemias of Pregnancy.—Dr. J. P. Hedley of London said that normally no creatin was excreted, but, in pregnancy, a considerable quantity was excreted from the third month onward, and the same was the case in dogs and rabbits. It had been shown that there was a greater excretion in toxemia, but his own investigations proved that the reverse was the case. The normal amount in pregnancy was below 1 milligram in 10 c.c. of urine. The subject required further investigation.

Rashes Occurring During the Puerperium.—Sir John Byers of Belfast read this paper. He described the following: Iodoform rash, lysol rash, urticaria, sweat rash, and erysipelatous, and scarlatiniform rashes. With reference to the erysipelatous he said that the prognosis was much worse when it originated in the genitals, as from a torn perineum, than when it originated elsewhere. He went extensively into the etiology of the scarlatiniform rashes and concluded that most of these were septic in origin and that true scarlatina in the puerperium was rare.

Developmental Errors of Puberty.—Dr. Fothergill of Manchester read this paper. Under this heading he included: (1) Infantilism, (2) hypertrophy of the cervix, (3) menorrhagia of puberty. Under (2) he said that, clinically, the most striking instances of this were protrusion and ulceration of the cervix without cystocele. Under (3) he said that curetting of the uterus showed hypertrophy of the mucous membrane and he attributed the bleeding to insufficiently developed muscle in the wall of the uterus. He said that these cases were not influenced by drugs, and if treatment by rest in bed did not cure, it was necessary to perform curetting.

Medical Items.

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended Aug. 16, 1912:

A PRACTICAL METHOD OF PROPHYLACTIC IMMUNIZATION AGAINST TUBERCULOSIS.

WITH SPECIAL REFERENCE TO ITS APPLICATION IN CHILDREN.*

BY KARL VON RUCK, M.D.,

ASHEVILLE, N. C.

My studies of the subject indicated by the title of this communication were first undertaken eight years ago, believing then, as I do now, that the available preventive methods by the care of tuberculous excretions and by endeavors to increase the general resistance through improvement in nutrition and in hygienic environment, while greatly desirable, would not prove as effective as is necessary and as we had hoped them to become when the causative relation of a specific microorganism was demonstrated by Robert Koch thirty years ago. My hope of finding a method of protecting the human organism specifically in a similar manner as we have been able to do against smallpox, found some support in the more or less effective protective effect from vaccination of lower animals, especially young cattle which had been shown by von Behring and others, and in the demonstration of specific antibodies in the sera of tuberculous patients after more or less prolonged treatment with products of the specific bacillus, made possible by the labors of Koch, Bordet and Gengou, Wright, Wassermann, and others.

I am not aware that any actual attempt has heretofore been made public to apply the principles of active immunization as a prophylactic measure against tuberculosis in the human subject, although we find occasional suggestions and recommendations of certain methods to this end in tuberculosis literature. Thus Heubner recommended the prophylactic application of tuberculin in young children soon after its discovery; von Behring in 1903 expressed the hope that the feeding to nurslings of milk from immunized cows would afford them protection against later infection. Calmette in 1904 proposed the oral administration of dead tubercle bacilli and again recently of non-virulent living bacilli of bovine origin, and in 1906 a similar proposition came again from von Behring, he then advocating the oral administration of a tubercle bacillus emulsion which he called Tulase, for prophylactic immunization of infants. Other writers have made similar suggestions. The report of Webb and Williams made last year upon the supposed immunization of two children of tuberculous parentage by repeatedly inoculating them with increasing numbers of living virulent tubercle bacilli needs no consideration here, as no proof of induced immunization was supplied and would not, even if they had shown the accomplishment of their object, inasmuch as their mode of procedure could not come within the limits of a practical method. The requirements of such a method I formulated in the beginning of my studies to be an available preparation or vaccine absolutely free from real or supposed danger, powerful enough to act by one or two applications, uniform in action by producing the desired immunity in all cases, simple enough in its technique to make it available for use of the general practitioner, without the necessity of elaborate investigations in selecting suitable cases.

Believing that the evidence I now propose to adduce justifies my claim that I have found a method complying with the requirements stated, I omit the details of my various investigations and experiments prior to its application in July of last year in children, the number of which up to April 1 has reached a total of 339, and proceed at once to the description of the preparation and then give the results shown in the immunized children by serum tests before and after each dose and at periods of from two to eight months thereafter; the observed action of their immune serum upon virulent tubercle bacilli *in vitro* and of my observations upon laboratory animals immunized with the preparation to a slighter degree as shown for the children by the study of Pfeiffer's phenomenon and of the protection afforded against intraperitoneal and other modes of virulent infection which in the number of tubercle bacilli used represented from one thousand to a hundred thousand and more times that necessary for the uniform production of a fatal result.

The vaccine ready for use contains per cubic centimeter 10 milligrams of proteins of tubercle bacilli and a small amount of their fatty extractives, proportioned quantitatively as follows: Protein No. 1, 0.25 milligram; protein No. 2, 2.75 milligrams; protein No. 3, 1 milligram; protein No. 4, 6 milligrams; fatty extractives, 0.01 milligram. In the adoption of the amounts of the several constituents present in the preparation I was governed by the study of their action when employed separately in the animal experiment as well as in some of the children. Finding that with the same doses but little effect was noted in the production of specific antibodies in the use of protein No. 1, this is present in the smallest amount, whereas protein No. 2, and especially the nucleoprotein designated as No. 4, appearing most effective, they are quantitatively in excess. The addition of the fatty extractives may eventually be found unnecessary, it appearing in my studies of complement fixation with the several constituents of the tubercle bacillus as antigens, that such fixation occurs with all of them inclusive of the fatty extractives with the sera of non-tuber-

*A summary giving the general results of the studies recorded in this paper was read before the Chicago Medical Society May 1, 1912, and appeared in the *Journal of the American Medical Association* May 18, 1912.

culous children after their vaccination with protein Nos. 2, 3, and 4, irrespective of the presence of one or the other of the fatty extractives in the preparation. In my preliminary animal experiments I have never been able to fully protect against virulent infection with the fatty acids, or the neutral fats, or with both of them combined, not even with large and often repeated doses, which were well borne by the animals; I also found that in the human subject any material increase of fatty extractives in the preparation over the amount present as given in the foregoing formula is liable to be followed after four to six weeks by local necrosis and abscess at the site of injection, and that its presence even in the very small amount retained is still responsible for the occasional occurrence of more or less circumscribed inflammation at the point where the injection is made. The reason why the fatty extractives are still retained is because I have observed my quantitative averages in complement fixation, with the fatty acids and the neutral fats present in the preparation to be slightly higher, as compared with averages when they have been omitted, but this difference can easily be a coincidence and depend upon the naturally present variability of the acme of the positive phase, the curve for which appears to be more or less independent for the different antigens, as will be shown in the tables which appear further on in this paper.

The chemical characteristics of the several proteins and the details of the production of the preparation sufficiently explicit to enable others to make an identical product appear in the foot notes below.*

My earlier precautions in endeavoring to exclude children already subjects of tuberculous infection proved unnecessary, as did also those of adopting very small doses in instances in which their examination justified the suspicion or the positive assumption, that a latent tuberculous process was actually present; having since found that like normal children they show neither severe reactions nor any other symptoms to the dose necessary to produce the desired amount of antibodies as shown in serum tests. I have, however, excluded from the rapid method such children as have evidence of active and progressive disease or have reached the stage of open phthisis, and in these treatment with small and repeated increasing doses was thought necessary in order to avoid accidents. The rapid method was also applied in ten adults varying in their respective ages from twenty-five to forty years, and though not included here, I may state that they responded in the same way as did the children. In the studies of the necessary dose, single or repeated, in the light of the age of the child, the presence or absence of tuberculosis, and the state of general nutrition, it was found that the smallest dose given of 0.1 c.c. of a 10 per cent. dilution caused the prompt development of the several antibodies, and an increase of the blood alkalinity, after a single administration. With larger doses, varying from 0.1 to 0.6 c.c. of the full strength, the quantitative determination of amboceptor after the first dose was the same as was shown thereafter when the dose was repeated with or without its further increase. The degree of serum agglutination was, however, in apparent relation to the size of the dose, and it increased with every subsequent dose. The blood alkalinity likewise increased on giving one or two additional doses, but not thereafter.

As regards the immediate effect of a given dose, irritation and inflammatory swelling at the point of injection occurred rarely. As a rule there was no other effect than a slight tenderness on pressure noted for twenty-four to forty-eight hours. No temperature rises were noted in normal children regardless of the dose given. In children suspected or positively determined to have previously acquired a tuberculous infection sore arms were noted more frequently but by no means uniformly, occasionally there was marked and diffused redness and swelling, which was then also attended with a moderate rise of temperature. Cold compresses to the arm controlled both symptoms, which subsided on the day following. In trials with the preparation containing no fatty extractives sore arms did not occur.

Focal reactions sufficiently marked to cause an increase of physical signs, in children who had

*The culture of tubercle bacilli used is of human origin, grown on bouillon, and has been perpetuated in my laboratory for the last ten years; it was apparently avirulent when first tested upon guinea pigs and has continued so to the present time. In the manufacture of the preparation heat has been avoided and the chemical effect of light excluded. No chemicals have been introduced in kind or concentrations that could injure, split, reduce, or alter the several constituents. The cultures having reached their maximum growth are collected upon a filter and washed free of adhering culture fluid until the filtrate gives no further biurette reaction. The bacillary mass is then transferred to a glass container immersed in distilled water containing 0.4 per cent. phenol, and with frequent stirring and shaking it is macerated for several days, when the filtrate obtained contains the protein designated as No. 1; chemically examined, it shows primary proteose, 25 per cent.; secondary proteose, 70 per cent.; peptone, small amount; reaction acid. After further washing with distilled water, the bacilli are dried and powdered, when their fat extraction follows; after drying they are again powdered and then partially extracted in distilled water yielding protein No. 2, this showing coagulable protein, 0.03 per cent. (estimated by nitrogen); primary proteose and deuterproteose in about equal amounts, total about 48 per cent., secondary proteose 50 per cent., peptone trace, phosphorus content 0.1 per cent., reaction alkaline.

The bacillary mass is again dried and powdered and suspended in 0.4 per cent. carbolized distilled water and then ground wet in glass capsules with agate marble, until repeated microscopic examinations no longer show a fragment or formed substance of the bacilli. Filtration through porcelain gives protein No. 3, in solution, differing from No. 2 by absence of coagulable protein, the relatively small amount of primary and increased amount of secondary proteose (75 per cent.) peptone is shown in small amount. The phosphorus content is 0.5 per cent., the reaction acid. Protein No. 4 passes the filter after the addition of an 0.4 per cent. solution of sodic hydrate and gives all reactions for nucleoprotein. The remaining bacillary residue amounting to about 5 per cent. weight of fat-free tubercle bacilli, is free from proteins (nitrogen determination), may contain traces of fats, and is probably cellulose. The secondary proteoses give reaction for sugar.

The fatty extractives of tubercle bacilli may be obtained separately as neutral fats and fatty acids by their saponification and subsequent extraction of the acid precipitate with alcohol and with ether, or in order to avoid undesirable chemical changes by saponification, the alcohol fats and ether fats may be obtained respectively by first complete extraction with ether, followed with alcohol, and vice versa, which to me appears preferable. When in solution they can be shaken out with distilled water, the latter holding about 0.5 per cent. in free suspension, which is opalescent in appearance in that concentration, the opalescence disappears in the concentration employed by me. The several proteins and fatty extractives having been obtained separately and having each been standardized, any free alkali in protein No. 4 having been neutralized by addition of a weak solution of HCl, just short of causing precipitation, the several constituents are assembled to represent the formula given in the text.

The precautions employed in preventing injury or undesirable modifications of the several bacillary products have not all been demonstrated as absolutely requisite for their highest efficiency, my purpose in their adoption having been to take no chances of an inferior preparation by their omission.

shown such in their lungs on a preliminary examination, could be accepted as present in several cases without being attended by fever excepting in one instance in which the coexisting inflammatory swelling of the arm could also have accounted for it. None of these immediate effects were in any sense troublesome, and, as stated, were exceptional in occurrence, and without any apparent relation to the size of the dose. Little influence if any has appeared to be caused by age, and while I have given no larger doses than 0.1 c.c., and as a rule only 0.05 c.c. to nurslings, the majority of all other children received 0.2 c.c. and from this amount to 0.6 c.c., the larger doses being given as a rule to children between ten and eighteen years of age. The subject of dosage requires further study; my immediate object having been to find that quantity which caused no serious disturbance and yet was effective. Having determined this, I adopted doses of one-twentieth or one-tenth of a cubic centimeter for nurslings, according to their ages, and of two-tenths to four-tenths of a cubic centimeter for older children for a single dose, while when two doses were given the first was one-half and the second dose was slightly less or the same as the single dose.

The satisfactory results observed in twenty consecutive children first immunized in Asheville made it desirable to study the method in a greater number in order to preserve me from erroneous conclusions. This I was enabled to do through the interest and courtesy of Dr. C. A. Julian of Thomasville, N. C., who is in medical charge of the children of the Baptist Orphanage at that place. Early in October of last year my studies were extended to them, and having fitted up a temporary laboratory, with the aid of Dr. Julian and of my assistant, Dr. A. E. von Tobel, preliminary examinations were made and recorded, including general appearance, present state of health, enlargement of lymph glands, physical signs in the lungs, the several tuberculin tests, blood examinations in case of apparent anemia, and for alkalinity and serum tests for specific antibodies, these examinations resulting in the selection of 262 cases for immunization. Adding to these 77 children immunized previously and since in Asheville, I have a total of 339, of which the results in the production of specific antibodies after the first dose and after each subsequent dose (when such was given) were determined; and in 300 children examinations were again made after periods of three to eight months, including this time physical examination of the chest in 118, for comparison with the records made prior to their immunization. When the taking of the blood specimen coincided with the so-called negative phase the examinations were repeated daily until the positive phase was in evidence, but it was not feasible to continue the examinations in all cases to obtain the results at the acme of the positive phase.

I have elsewhere called attention to the relation of the precipitin curve, to the opsonic index, and to amboceptor as shown by complement fixation, these giving, as a rule, the greatest value, when the precipitin curve is at the lowest point and vice versa, but it should be stated that this relation is not absolute in the sense that an immune serum of a certain case gives necessarily the same quantitative result on subsequent examinations, at a certain stage of the precipitin curve, or of the opsonic index. The quantitative variations in this respect seem to depend upon coincidence or otherwise of complement fixation with other constituents of tubercle bacilli, especially the fats, fixation with which in time of appearance, increase and subsidence appear to have a more or less independent curve, not necessarily corresponding with that of the opsonic index, or of the precipitins, suggesting a multiplicity of amboceptor. It may thus be shown that in the absence of complement fixation with tubercle bacilli emulsion and in the so-called negative phase, fixation can still occur with one or the other fatty constituents or with both, or more rarely with only one or the other of the several proteins; and my studies of these interesting phenomena, though by no means completed, show that serum specimens are occasionally taken from an immunized individual at the opportune time, when complement fixation shows the maximum for all constituents of the tubercle bacillus, in which case complement fixation with tubercle bacilli emulsion is liable to occur in higher serum dilutions than it does when such coincidence is less complete or absent.*

*Since the appearance of my preliminary report I have been in receipt of requests from several interested students for technical details for the determination of precipitins which they appeared to believe should quantitatively correspond with agglutinins, the latter being identical. Inasmuch as the technique followed in my laboratory does not differ essentially from that which all students in immunity appear to follow, I did not deem it necessary to encumber this, and much less the preliminary report with details, which may be learned in any of the standard works on immunity, and which would be unnecessary for those capable of controlling my observations if they felt so inclined. To answer such and others who desire more technical details, I wish to add them sufficiently explicit as to show that I have not departed from the usual methods. For the determination of the precipitins, a series of small test tubes is prepared corresponding in number to that of the serum dilutions, and into each is measured 1 c.c. of a solution of either one of the tubercle bacilli proteins No. 2, 3 or 4. To each tube is added an equal quantity of the particular serum dilution to be tested, and after shaking and capping the tubes they are placed in a thermostat and kept there at a temperature of 37° C. for five or more hours (precipitation occurs also at a room temperature in 12 to 24 hours), when the tubes are ready for reading the results. The precipitate is visible in the bottom of the test tube and slight agitation of the tube raises it into the clear fluid above and thus makes it still more apparent. The percentage of protein in the solution makes no difference, the precipitate coming from the serum and not from the antigen. We use either an 0.1 per cent. or an 0.01 per cent. solution; the stronger one gives a larger amount of the precipitate in the tubes containing serum in the lower dilutions. All blood sera give positive tests for precipitins. In studies of normal human serum, especially of specimens of new-born children, I found that, as a rule, a precipitate does not occur in dilutions higher than 1:200, and but rarely as high as 1:400.

Sera of tuberculous patients and of vaccinated children give precipitates in much higher dilutions, sometimes of 1:2000, 1:3000, or even 1:5000; the highest values were noted most frequently in active progressive cases of tuberculosis and after diagnostic or therapeutic doses of tuberculin preparations. Finding that complement fixation is negative, or but rarely positive, with sera that gives a precipitate in dilutions as high as 1:1600, and that at this point the opsonic index is, as a rule, below normal, we do not as a rule make tests with higher dilutions, and finding, further, that the serum dilutions in which precipitin is shown correspond inversely with the opsonic index of Wright and with quantitative determinations of complement fixation, I have for several years used the precipitin curve instead of the opsonic index for a guide, as an equally reliable and much quicker method. Its advantage I believe will be appreciated by others, especially when the daily examination of 50 or more blood specimens is contemplated. In reference to the technique used in my laboratory in the quantitative determination of specific amboceptor by complement fixation, I take it for granted that the reader needs no explanation of the theories and principles involved and refer in this respect to text books on immunity in general and to the studies of Bordet and Gengou, or of Wassermann and Bruck in particular. I

The following tables are copies of individual records which illustrate the relation and variability of complement fixation with the different antigens more fully.

The records of the children under consideration were studied collectively by tabulations in separate groups, according to age, sex, and general nutrition, absence or presence of tuberculin reactions and of serum agglutination, presence of enlarged lymph glands, and of physical signs in the lungs, in order to show whether or not any difference was apparent in their response to vaccination after one or more doses, immediately or on subsequent examinations, without, however, enabling me to show enough with the present number of children, to justify a positive conclusion that one or the other groups showed different results. The 339 immunized children represent all ages from 2 months to 18 years. Their preliminary examinations justified the following grouping as regards the presence or absence of tuberculosis: Normal (*i. e.* apparently free from tuberculosis), 85; suspects (in which the evidence of existing infection was incomplete), 94; tuberculous (in which the evidence of existing latent tuber-

may, however, say that in conformity with the common practice and the need of precautions, all antigens are standardized and frequently controlled, and that, like other observers, we used half the amount of the particular antigen which caused self checking; our hemolytic system is rabbit serum lytic for calf cells, each of them used fresh, and with the hemolytic power determined from day to day, and again controlled with each series of experiments. I may further add that the number of blood specimens examined in my laboratory for precipitins and for complement fixation amounts now to tens of thousands, and that in our clinical and experimental studies we did not omit to regularly control our technique in regard to the antigens and the hemolytic system and by occasionally checking our observations by duplicate tests made with the same serum specimens and read by the same and by independent observers, and that no results were accepted when anything was at all suggestive of error. Slight differences in readings have occasionally occurred with the same serum specimen when these were made by two or more of our staff independently of each other. Such occasional differences must be expected, depending as they do upon individual judgment, as, for instance, accepting a trace or none of a precipitate, partial or complete checking of hemolysis, complete or only partial agglutination, etc., in a particular tube. Like slight differences may occur, as is well known, in thus controlling the results of differential counts of white blood cells, in arriving at the opsonic index by counting the number of phagocyting cells, without detracting from the practicability and value of the method.

In a duplicate test of hourly examinations for complement fixation, as shown in Table 3, each observer prepared and examined independently 360 tubes. In only four of them did such a difference occur; in reading all others the observations tallied. Real errors in observations can as a rule be avoided by sufficient vigilance, and especially by the absolute rule never to make such tests without proper control tubes. This may be illustrated by an observation made in my laboratory on the day of this writing, of an unexpected and so far unaccounted for failure in the hemolytic system which, without proper control, could have caused the acceptance of complement fixation and of its coincidence with all antigens in a high degree, when the immune serum should also have been lytic *in vitro;* while the precipitin curve stood at 1200, indicating that the blood specimen was taken in the negative phase, whereas, in fact, the serum had no power to fix complement at all. The hemolytic action of the fresh serum of a rabbit upon fresh well washed calf cells had just been tested, and the hemolysis was complete in 15 minutes. With the tubes prepared for the complement fixation test was incubated a control tube which contained the rabbit serum alone and when, after two hours' incubation at 37° C., the calf cells were added, the rabbit serum failed to cause complete hemolysis as had been expected, and of course complete hemolysis also failed to occur in the tubes prepared for testing the immune serum. Additional trials gave the same results with the serum from this particular rabbit; it still caused complete hemolysis in 15 minutes without prior incubation and failed to do this after the serum remained in the thermostat at 37° C. for one or two hours.

The serum of another rabbit tested with the same calf cells acted normally regardless of its prior incubation. Why incubation for two hours at 37° C. should cause the partial loss of the specific amboceptor or of the complement in the serum of this particular animal remains to be explained; the observation is, however, suggestive of the vigilance required to prevent error.

culosis was thought to be conclusive), 160. More or less deficiency in general appearance and especially in nutrition was noted in most of the tuberculous, and not infrequently in those classed as suspects, while the normal children did not, as a rule, lack in this respect. Of those classed as tuberculous physical signs could be shown in chest examinations in 118, slight and confined to one side in some, more marked or on both sides in others—mostly girls belonging to ages between 10 and 18. Physical signs were absent in suspects; instead, the finding of enlargement of lymph glands was the rule, more frequently of the cervical and axillary groups, often both, sometimes the inguinals were also enlarged. Enlarged faucial tonsils were frequently noted. No marked deviations from normal were observed in cell counts or hemoglobin determinations in instances where these were made. The determinations in blood examinations, including alkalinity, amboceptor, and opsonins before and after each dose in the 339 children immunized and in the 300 children re-examined represent a total of over 3000 individual examinations.

Tabulations of the results give the following averages:

BLOOD ALKALINITY.*

	Average	Minimum	Maximum
Preliminary examinations	0.85	0.60	1.00
Examination after first dose	1.05	0.90	1.20
Examination after second dose	1.20	1.05	1.30
Examination 3 to 8 months later	1.20	1.10	1.30

*The blood alkalinity was estimated by Dare's method, which is based on a normal of 266 milligrams sodio hydrate per 100 cubic centimeters of blood. We have repeatedly controlled the results obtained by Dare's with trituration methods and found no material difference. Appreciating that no method is absolutely accurate, that of Dare has the advantage of rapidity and appears to serve for comparative studies as well as any other.

†The minimum of 1:25 occurred in normal children who had received only one dose.

‡Preliminary examinations in complement fixation were made in 110 children, most of them suspected or believed to be tuberculous. In 25 of the normal children, and in the study of complement fixation of serum specimens from

In eighty children and several adults the amboceptor studies included observations with other bacillary constituents as antigens, namely, the neutral fats and fatty acids, and several of the proteins in addition to emulsion of tubercle bacilli of human and of bovine origin. The preceding tables 1, 2 and 3 are illustrative of the results obtained.

Precipitins.—The observations of the power of the sera in dilutions of 1:100-200-400-800-1600 to precipitate a 1/100 of 1 per cent. solution of tubercle bacilli protein were useful chiefly as a guide to the negative and positive phases. In the study of my tabulated results it appears that the precipitin curve in the tuberculous is, as a rule, higher, more variable, does not reach the low point as frequently and in some instances not at all until several months after immunization.

The Opsonic Index.—The opsonic index in cases in which it also was studied in the preliminary examination, was practically normal for normal children. For tuberculous children and suspects the average was 0.85, with a minimum of 0.50. Studies of so-called immune opsonins with normal salt solution as a control show that the specific opsonic power of the serum likewise varies inversely with the precipitin curve and runs nearly parallel with the degree of complement fixation of a particular specimen. The normal salt level was reached most often with serum dilutions of 1:500 to 1:1000 or over when complement fixation occurred in serum dilutions between 1:20 and 1:40. With positive fixation in dilutions of 1:8 or 1:4 the salt level was reached sooner, as a rule in dilutions of 1:100 to 1:300, while in the absence of complement fixation the salt level was reached in serum dilutions of 1:30 to 1:100. The influence of immunization upon children classed as suspects, or as apparently tuberculous in their examinations three to eight months later, was particularly shown by improvement in their general appearance when this had been found impaired on their preliminary examination, not only as observed by comparing the records but also as observed by those in immediate charge. Gain in weight occurred almost uniformly, amounting in many instances to ten to forty pounds, and therefore in excess of the normal increase of a growing child. In regard to the effect upon enlarged lymph glands, while diffi-

100 newborn children, for other purposes, complete fixation was never observed in serum dilutions of 1:4, a trace only being shown in two instances. In the groups of children probably tuberculous and accepted as such, the 85 determinations made showed complete fixation with a low precipitin curve and with serum dilutions 1:4 in six, and a trace in 14 cases.

Explanation of Plate.

A and B represent tubercle bacilli, from control tubes after incubation for 24 hours: A with normal salt solution, B with normal human serum. The bacilli are unchanged.

No. 1 shows the result obtained with immune serum from a child vaccinated six months ago; the blood specimens taken in the negative phase; serum precipitation in dilutions 1:1600; complement fixation negative with all antigens. A slight lytic effect is shown by the beaded and faintly stained appearance of some of the bacilli seen among others, which appear unchanged. A few fragments and granules are also present.

No. 2 (a). Result with immune serum from a child vaccinated six months ago. Precipitins 1:800, complement fixation complete with T. B. Emuls. as antigen 1:4, and only a trace or negative with all other antigens. To the right of the field may be noted a dark mass which in the stained slide is of deep red color, which is acid fast and represents free fat, dissolved out of the bacilli as indicated by the faintness of their stain in most of the remaining rods and in the more numerous fragments and granules. Some of the rods are beaded. No. 2 (b). Result with the same specimen of immune serum used in obtaining Field 2 (a) renewing it twice during incubation. The field shows entire disappearance of whole rods, unless hidden by several clumps of deeply stained free fats. There are many fragments, all more or less beaded, and numerous free granules, neither of which retained the stain, as well as did the clumps of fat and the fragments which they enclose.

No. 3. Immune serum from a child vaccinated eight months ago. Precipitins 1:800. Complement fixation complete with T. B. Emuls. 1:4, fatty acids 1:4, neutral fats 1:4, negative or only a trace with other antigens. This field shows to the left a deeply stained mass of free fats which is diffused through the other parts in a thin layer appearing in light pink in the stained slide. No whole rods are present, beading of the fragments is well marked, free granules are numerous. The beading of fragments is most distinct in those which retained the stain indifferently.

No. 4. Immune serum from a child vaccinated eight months ago. Preciptins 1:400, coinciding complement fixation with all antigens. (T. B. Emuls. 1:8, fatty acids 1:4, neutral fats 1:4, Protein No. 2 1:8, Protein No. 4 1:8.) The field shows free fats diffused and in a thin layer throughout; in the center is a mass of fine acid fast granules, and other fields like the present were found in this slide. No bacilli were found, either in cocci chains, or in larger fragments than those present.

No. 5. Immune serum from child vaccinated eight months ago. Precipitins 1:100, maximum coincidence of complement fixation in high degrees. (T. B. Emuls. 1:40, fatty acids 1:20, neutral fats 1:8, Protein No. 2 1:20, Protein No. 4 1:20.) The result shown was obtained after incubation for one hour. The left portion of the field shows a thick mass of deeply stained fats; the right portion shows a thin, diffused layer in which a few very fine, isolated granules were shown with the microscope, but are not as clearly apparent in the microphotograph. This field was selected as it was the only one showing a trace of a formed element; all other fields showed nothing, excepting more or less deeply stained fat.

No. 6. Immune serum from a child vaccinated seven months ago with Protein No. 4. Precipitins 1:400. Complement fixation with T. B. Emuls. 1:8, fatty acids 1:4, neutral fats 1:8, Protein No. 2 1:8, Protein No. 4 0. The field shows several dark masses of deeply stained fats, within which are fragments of bacilli and granules; the latter are not well shown by the microphotograph, nor are others which the mounted slide shows in the pinkish diffused fat in the rest of the field. The field is reproduced to show that the nucleoprotein alone, the same as Protein No. 2, is effective for immunization, and that though no fatty extractives were used in the children from whom this and the serum specimen of the following field No. 7 were obtained, their sera acquired the power to fix complement with the fats and have lytic power also.

No. 7. Immune serum from a child vaccinated seven months ago. The result shown is of interest inasmuch as complete complement fixation was absent in serum dilutions 1:4, with all other antigens excepting the fats, being complete with fatty acids 1:8, neutral fats 1:4. Of further interest is that, like in the preceding field, the child was vaccinated with a single one of the proteins (No. 2) without addition of fatty extractives. Diagonally across the field are seen fragments and granules of tubercle bacilli more or less embedded and surrounded by free fats, which are likewise diffused through the entire field. A few cocci-like chains may be observed; there are many free granules faintly stained. No whole bacilli were found in other fields, and the degree of lytic action appears to correspond with No. 4.

No. 8. Immune serum from child vaccinated eight years ago with Protein No. 2. The serum taken at a maximum coincidence of complement fixation with all antigens shown in observation of April 7 in Table No. 2 (T. B. Emuls. 1:40, fatty acids 1:4, neutral fats 1:4, Protein No. 1 1:8, No. 2 1:20, No. 3 1:20, No. 4 1:20.) The field shows two heaps of fine granules in deeply stained free fats, which cannot be discolorized with acids. These and other free granules were but faintly stained with fuchsin and took the counterstain. Similar fields were found in this and other slides. The lytic action of this serum specimen is of interest, inasmuch as the immunization of this child dates back eight years.

PROPHYLACTIC IMMUNIZATION AGAINST TUBERCULOSIS.—*von Ruck.*

cult to compare, I can state that in numerous instances none were found when their presence had been recorded, or only one or a few were found when the records showed many. More accurate comparison was possible in regard to physical signs, especially when these had been recorded upon a special chart. Frequently they had entirely disappeared, and there was not a single instance in which a comparison did not indicate unmistakable improvement. The inclusion of the children suspected or accepted as being tuberculous in this study appeared desirable in order to show the possible necessity of excluding them from the rapid method of immunization with a single dose. I consider it particularly fortunate and important that it was not found necessary to proceed in such with greater caution by using very small, repeated and increasing doses in order to avoid severe alarming and possibly dangerous reactions, since such a necessity would have required all our diagnostic resources, and would thus have greatly limited the employment of the rapid method in the hands of the general practitioner.

Having shown the prompt and uniform development of all specific antibodies after a single dose of the preparation, by the method described and the induced immunity being still evident in like degree in every case re-examined three to eight months later and after a lapse of eight years in the one case in which I made the first trial, and having further confirmation in regard to the endurance of the induced immunity by the fact that I have in numerous instances been able to show the same permanency in therapeutic immunization with one of the constituent proteins after periods of two to fourteen years, I proceed now to the relation of experimental studies designed to show that the method is ample to protect against virulent infection. My bacteriolytic studies with immune serum designed to show this were not immediately successful in results, and not until I had learned to select the serum specimens at the right time of complement fixation with the several antigens, as indicated in the preceding tables, and until instead of inactivating and adding fresh complement, the immune serum was used active and in the fresh state. Since then I have had no difficulty in obtaining a lytic effect of a greater or less degree, this corresponding practically to the amount of free amboceptor for the different antigens shown in the serum specimen; after numerous observations in vaccinated children and in clinical cases I find that the degree of lysis can serve as an index for the presence and coincidence of specific amboceptor. I have for the present adopted a scale of 0 to 5; the zero which corresponds to a negative result is shown in my control slides and is illustrated in the two fields marked A and B, in which the bacilli appear unchanged and are normally stained. Fields No. 1 to 5 show an increasing lytic effect to the complete absence of any formed elements, fragments, or granules, nothing remaining but the free fat liberated by the lytic serum, which still retains the stain. The morphological changes of the bacilli, shown by faintness of stain, tendency to take the counterstain, beading, breaking up into fragments and granules free or simulating short chains of cocci, are of interest in connection with the meaning of such forms, when found in tuberculous lesions, sputum, urine, and pus, and support the opinion of those who believe that they represent evidence of degeneration. All these forms may be observed in the accompanying reproductions of microphotographs made from my mounted slides intended to show the various degrees of lysis obtained with immune sera, according to the amount of free amboceptor present at the time the blood specimens were taken from vaccinated children.

The technique for the experiment is the usual one.*

The accompanying plate shows reproductions of microphotographs with magnifications of 1000 diameters of fields from mounted slides prepared as heretofore described.

Examinations of the lytic effect of immune sera were also made in the hanging drop, the tubercle bacilli having first been faintly stained with methy-

*A suspension of virulent tubercle bacilli from a rapidly growing culture is prepared with normal salt solution, of which two drops from a small pipette represent 0.01 milligram of tubercle bacilli which have been pressed as dry as possible between clean sterile filter paper. Excessive grinding must be avoided to prevent the presence of fragments, and yet freedom of clumps of bacilli, as shown by microscopic examination, must be secured by frequent use of the centrifuge, separation of the clear fluid and regrinding of the residue. It is, however, preferable to leave a few adherent bacilli, rather than to produce fragments, inasmuch as some clumping is likely to occur anyway, on the addition of the immune serum which causes more or less agglutination; and the greater the latter is, the morer rapidly will clumping occur, and the more will it interfere with the disintegration of the bacilli, as the clumping prevents the free access and contact of the serum. I find that with an immune serum of low agglutinating power, in serum dilutions 1:25 to 1:50, little or no clumping occurs. This was the case with serum specimens from children who received only one dose of the vaccine. After preparing one or more control slides of the emulsion, two drops each of the emulsion and of the active fresh, immune serum are placed in each of two small, narrow test tubes, with or without two drops of additional complement which we find has little if any influence. A control tube is prepared in which the immune serum is omitted and normal salt solution is substituted, and if normal human serum (*i.e.* from an untreated non-tuberculous subject) is available, another control tube is made with normal serum, known to be so, by repeated previous tests for complement fixation, having been negative in results, when the precipitin curve is not over 200. The little tubes are now well agitated and capped or corked to prevent evaporation; they are placed in the thermostat at a temperature of 37° C., where they remain for 24 hours. When the serum shows a high degree of coinciding complement fixation, complete lysis excepting of large clumps may be noted already after an hour or two, and even the clumps may have given place to an extremely fine mass of granules in the course of the first three hours of incubation. With lower powers of complement fixation, the lytic effect *in vitro* may be more or less enhanced by repeated addition of fresh active immune serum, during the time of incubation. Addition of more fresh complement from animals has no material influence. After incubation, the tube contents are agitated with a sterile looped platinum wire, and by shaking, and with this wire specimens are removed and prepared for microscopic examination. We think that Spengler's picric acid stain gives as good, if not better, results than does the Ziehl stain, and that staining after Gram is not more effective in demonstrating the bacillary residue. Two or more specimens prepared with the same immune serum show, as a rule, the same degree of lysis; it may, however, happen that one shows slightly more or less, which I believe depends then on the degree of agglutination and clumping. The control tubes show no morphological change of bacilli and do not differ from the control slide prepared from the emulsion before the test is made.

If the virulence of the tube contents is to be tested and compared they are drawn up with the needle of the hypodermic syringe to be used for infection, and after rinsing the empty tube with several drops of normal salt solution and adding them to the content of the syringe; the fluid is injected into the peritoneal cavity of a normal guinea pig, weighing about 400 grams. Very small animals are liable to die of anaphylactic shock and even full grown animals may thus be lost, when the lytic effect of the immune serum has been complete, as will be noted in my experiments to be described further on.

lene blue. The several tests varied with the degree of complement fixation, and in an observation with a serum specimen in which this was complete with all antigens the result was as follows: After 15 minutes, no change; after 30 minutes, slight changes; after 45 minutes, bacilli appear broken up, an occasional rod is still visible; after 60 minutes, the field has the appearance of being composed of cocci.

Animal Experiments.—Normal animals were infected intraperitoneally with the contents of tubes used for bacteriolytic studies *in vitro*, and to save repetitions I may mention that unless otherwise stated, each tube contained 0.01 milligram of living virulent tubercle bacilli in suspension, plus the fresh active immune serum to be tested, with normal fresh complement added when the tube was prepared, while in control animals normal human serum or normal salt solution was substituted for the immune serum, incubated as were the other tubes.

Group I.—Control animals. Guinea Pig. No. 1: Infected with contents of a normal serum tube; weight, 570 grams. Death occurred 41 days after infection; weight, 500 grams. Autopsy: Tuberculosis of liver, spleen, kidneys, and lungs. Tuberculous peritonitis, mesenteric, retroperitoneal and bronchial glands enlarged, and tuberculous, many of them caseous, all showing well stained tubercle bacilli in smears. Guinea Pig No. 2: Infected same as No. 1. Weight 660 grams. Death occurred 41 days after infection, weight 520 grams. Autopsy: Generalized tuberculosis, practically the same findings as in Guinea Pig No. 1. Guinea Pig No. 3: Infected same as Nos. 1 and 2. Weight 470 grams. Death occurred 42 days after infection; weight, 320 grams. Autopsy: Generalized tuberculosis, same findings as in No. 1; in addition the inguinal glands are also tuberculous. Guinea Pig No. 4: Infected with contents of tube, in which the normal serum was substituted by normal salt solution; weight 540 grams. Death occurred 32 days after infection. Weight 440 grams. Autopsy: Generalized tuberculosis, practically same findings as in other control animals. Circumscribed abscess at peritoneal point of infection puncture.

Group II.—Experiments with immune serum: Two normal animals infected with tube contents, the immune serum taken in the positive phase but having been inactivated and normal rabbit complement added, without, however, any lytic action having been demonstrable *in vitro*. Guinea Pig No. 1: Weight 650 grams. Death occurred 86 days after infection. Weight 500 grams. Autopsy: Cold abscess at site of infection; tuberculous peritonitis slight in degree, fine adhesions; inguinal lymph glands caseous; bronchial glands enlarged and tuberculous; few tubercles are found in omentum, mesentery, liver, and lungs; acute pneumonia of both lower lobes non-tuberculous in nature, which caused death. Guinea Pig No. 2: Weight 860 grams. Death occurred 76 days after infection. Weight 605 grams. Autopsy: Inguinal and axillary glands enlarged and caseous, caseation at site of infection, local tubercle of peritoneum adjacent. Scattered tubercle in spleen and liver, one tubercle upon peritoneal surface of left kidney; mesenteric, retroperitoneal, bronchial and mediastinal glands enlarged. Scattered tubercle in both lungs.*

*A third animal belonging to this group is still living, three months after infection; the animal is, however, losing in weight and shows otherwise that it is tuberculous and that death will occur in the near future.

Group III.—Ten animals belonging to this group were infected intraperitoneally each with the contents of a tube which, after incubating a suspension of 0.01 mgr. virulent tubercle bacilli with fresh active immune serum from vaccinated children and normal rabbit complement, showed on microscopic examination degrees of lytic action corresponding to the numbers 1 to 5 of the accompanying plate. Five of the animals were killed and the result of their autopsies follows. Five of the animals are still living and in perfect condition. Guinea Pig No. 1: Weight 510 grams. Killed 84 days after infection. Weight 700 grams. Autopsy: A firm nodule, size of half pea, in fat near the attachment of the mesentery is all that is found. The nodule shows fibrous structure, a few round cells between fibers, no giant cells, no tubercle, no tubercle bacilli or granules. Guinea Pig. No. 2: Weight 550 grams. Killed 84 days after infection. Weight 745 grams. Autopsy: Two small hard nodules in omentum, with adhesion to diaphragm; the larger one has a fibrous capsule and a minute caseous center, smears from which show very few acid fast granules; the other nodule is fibrous in structure throughout. Guinea Pig No. 3: Weight 565 grams. Killed 84 days after infection. Weight 725 grams. Autopsy: Nothing found but one small nodule (pin point in size) in the mesentery, which is of fibrous structure throughout. Guinea Pig No. 4: Weight 820 grams. Killed 86 days after infection. Weight 770 grams. Autopsy: Three fibroid nodules in omentum; two similar ones the size of pin's head in the liver, one same size in the left lung. The omental nodules have a fibrous capsule with small caseous centers, traversed by tissue fibers, a few leucocytes, but no tubercle bacilli or granules can be found. The nodules from the liver and left lung are calcified. Guinea Pig No. 5; Weight 530 grams. The immune serum in the tube used was taken in the negative phase; no complement fixation occurred in 1:4 serum dilution with any of the antigens, only traces or incomplete fixation. The tubercle bacilli were scarcely changed at all. The object of the experiment was to show if tubercle bacilli would nevertheless become sensitized, and if this could be demonstrated by observation in the study of Pfeiffer's phenomenon. After 1 hour, numerous free bacilli in the exudate and but few in the leucocytes; after 3 hours, few free bacilli, numerous bacilli in the leucocytes; after 24 hours, occasionally a free bacillus; few bacilli, more granules in leucocytes. Killed 70 days after infection. Weight 680 grams. Autopsy: Only one enlarged bronchial gland was found; this showed round cell infiltration, no tubercle, no giant cells; smears from gland residue after dissolving in antiformin, negative.

Group IV.—This group includes 10 guinea pigs which were infected same as those of the preceding group, but the lytic action of the immune serum *in vitro* being complete, or nearly so, as shown in numbers 6, 7, 8 of the plate. Of these 10 pigs 5 were found dead 12 hours after infection; their autopsies showed the heart distended with blood, the lungs congested and a small amount of serous exudate in the peritoneal cavity, smears from which showed neither tubercle bacilli nor granules. The sixth pig died under rapid loss of weight (100 grams) on the sixth day; its autopsy showed exudative peritonitis, smears from the exudate were negative as to finding of tubercle bacilli or granules. The other four pigs are living, and are gaining in

weight, three months after their infection. The five pigs which were found dead 12 hours after infection were quite cold and stiff, suggesting that death had occurred a few hours only after the contents of the tubes had been injected into the peritoneal cavity, a result which can be best explained by bacterial anaphylaxis, against which I thought that I had guarded, by the small dose of 0.01 milligram of tubercle bacilli used in the experiment, Aronson in a recent contribution giving 10 to 20 milligrams as the minimum for such results. The fatal effect of the comparatively extremely small number of tubercle bacilli having undergone complete lysis, appears to confirm those who consider the presence of specific amboceptor of material influence in the production of the phenomenon.

Group V.—This group comprises 5 rabbits infected intraperitoneally with the content of tubes after incubation for 24 hours with immune serum of 1/10 milligram of virulent tubercle bacilli of bovine origin, the experiment being designed to show the effect upon tubercle bacilli of bovine origin. Rabbit No. 1: Control. Weight 1980 grams. (Normal salt solution was substituted for immune serum.) Death occurred 47 days after infection. Weight 1850 grams. Autopsy: Generalized tuberculosis involving both lungs, liver, and kidneys, axillary, inguinal and bronchial glands enlarged and tuberculous. Rabbit No. 2: Control. Weight 2050 grams. (Normal human serum from a new-born child was substituted for immune serum.) Death occurred 48 days after infection. Weight 1900 grams. Autopsy: Generalized tuberculosis of all organs, practically the same as found in Rabbit No. 1. Rabbit No. 3: Control. Weight 1660 grams. (Normal human serum from an adult was substituted for immune serum.) The animal lost 90 grams in weight in the first week, then gained. Killed 111 days after infection. Weight 1860 grams. Autopsy: Abdominal organs normal, no lymph gland enlargement, excepting one bronchial gland; in lower lobe of the left lung are found numerous nodules, showing epitheliod and giant cells; they are well encapsulated, in some of them bands of fibrous tissue are interspersed between the cells. No caseation was found in any of them, nor could tubercle bacilli be demonstrated in sections. After dissolving a portion of the involved lung tissue in antiformin examinations of smears made from the residue gave negative results. The enlarged bronchial gland was found to be fibrous in structure but still showing round cells between the tissue fibers, no tubercle or giant cells and no tubercle bacilli were found in sections, and smears from antiformin residue gave negative results. The animal was evidently recovering from the infection. Rabbit No. 4: Weight 2270 grams. Infected with tube containing 1/10 milligram virulent tubercle bacilli of bovine origin, after having been incubated 24 hours with serum from an immunized child showing complement fixation 1:10 with Tubercle Bacilli Emulsion (no other antigens employed). Killed 80 days after infection, weight 2320 grams, after a loss of 100 grams during the preceding week. Autopsy: Nothing found; all organs and lymph glands normal; the liver showed numerous cysts of coccidium cuniculi, which account for recent loss of weight. Rabbit No. 5: Weight 1960 grams. Infected same as rabbit No. 4; the human serum used was obtained from an immunized adult and showed complement fixation 1:20 with tubercle bacilli emulsion (no other antigens employed). Killed 111 days after infection. Weight 1600 grams. Autopsy: Same result as in rabbit No. 4, the liver showing likewise coccidium cysts, only more numerous. These experiments I hope to repeat with a larger number of animals, in a contemplated study of the relation of bovine infection to human tuberculosis, and especially in regard to the comparative resistance of infants and adults. *Experiments with immunized animals:* In the immunization of guinea pigs and of rabbits we failed to demonstrate specific amboceptor after a single dose. Repeated doses of from 0.1 to 1.0 c.c. were given during six weeks before complement fixation in serum dilutions of 1:4 and in one or two animals of 1:8 could be shown. There was, however, a steady increase of agglutinins, and the precipitins varied, as observed in the human subject. Complement fixation with other antigens was not tried in all of them, because of the difficulty to get enough serum from such small animals. The immunization of rabbits appears to require still larger doses. Under a gradual increase to 1.0 c.c. we had in only one of thirty animals obtained complement fixation with its serum, and at that time the whole number was lost by an epidemic of pneumonia.

Group VI.—This group was designed for the study of Pfeiffer's phenomenon and comprises eight guinea pigs, six of them immunized, and two normal animals used for controls. The observations made and the autopsies of the controls and of five immunized animals follows below. The sixth animal, having then a litter of young, was allowed to live, and is still living and in good condition after giving birth to another litter of young. It will be noted that the disintegration of the tubercle bacilli occurred after phagocytosis, within the leucocytes. Guinea Pig. No. 1: Control. Infected intraperitoneally with 10 mgr. virulent T. B. Weight 560 grams. Pfeiffer's phenomenon: After 1 hour, many tubercle bacilli free, few in leucocytes; after 3 hours, many tubercle bacilli free, few in leucocytes; after 24 hours, many tubercle bacilli free, more numerous in leucocytes, no granular disintegration. Death occurred 30 days after infection. Weight 380 grams. Autopsy: Generalized tuberculosis, involving the peritoneum, omentum and mesentery, the abdominal organs being involved to a greater degree than the lungs. Guinea Pig No. 2: Control. Infected with 5 milligrams of tubercle bacilli, same culture. Weight 580 grams. Pfeiffer's phenomenon: After 1 hour, many tubercle bacilli free, few in leucocytes; after 3 hours, many tubercle bacilli free, few in leucocytes; after 24 hours, many tubercle bacilli free, many in leucocytes; no granular disintegration. Death occurred 41 days after infection. Weight 480 grams. Autopsy: Generalized tuberculosis, same as in animal No. 1, but with greater involvement of the lungs. Guinea Pig No. 3: Immunized. (The serum of the animal shows complement fixation complete with T. B. Emulsion 1:8, with fatty acids 1:8, with neutral fats 1:8, serum agglutination 1:150, precipitins 1:400.) Infected intraperitoneally with 10 milligrams tubercle bacilli, same culture as used in controls. Weight 630 grams. Pfeiffer's phenomenon: After 1 hour, few tubercle bacilli free, many granules and few T. B. in leucocytes; after 3 hours, no tubercle bacilli free, many granules, no bacilli in leucocytes; after 24 hours, no free bacilli nor granules; nothing in leucocytes. Killed 70 days after infection. Weight 750 grams. Autopsy: A small fibrous nodule in mesentery; one upon free edge of the liver; one enlarged hard bronchial gland. The nodules and the lymph gland show

only fibrous structure. No evidence of tubercle or caseation; no tubercle bacilli. Guinea Pig No. 4: Immunized. (The serum of the animal shows complement fixation complete with T. B. Emulsion, 1:4; no other antigens used; precipitins 1:800; serum agglutinution 1:150.) Infected same as No. 3. Weight 420 grams. Pfeiffer's phenomenon: After 1 hour, few tubercle bacilli free, few in leucocytes; after 3 hours, few tubercle bacilli free, few T. B., many granules in leucocytes; after 24 hours, nothing free, few granules in leucocytes. Killed 90 days after infection. Weight 550 grams. Autopsy: At point of infection puncture a small adhesion to a loop in intestine. Two small firm nodules in omentum, with adhesion to stomach and liver. Nodules show a thick, fibrous capsule, one is centrally caseated; caseous material showing few acid fast granules; the other nodule is fibrous in structure throughout. Guinea Pig No. 5: Immunized. (The animal's serum shows complement fixation with T. B. Emuls. 1:8; no other antigens used; precipitins 1:800; agglutinins 1:150.) Infected same as No. 3. Weight 560 grams. Pfeiffer's phenomenon: After 1 hour, few T. B. free, few T. B., many granules in leucocytes; after 3 hours, No T. B. free, only granules in leucocytes; after 24 hours, nothing free, very few granules in leucocytes. Killed 90 days after infection. Weight 635 grams. Autopsy: One small nodule in peritoneum at point of infection puncture, with adhesion to tip of right seminal vesicle. One small nodule in omentum, another upon lower surface of diaphragm, with adhesion to liver. All three nodules have a thick fibroid capsule, with caseous center showing acid fast granules. Guinea Pig No. 6: Immunized. (The animal's serum shows complement fixation complete with T. B. Emulsion 1:8; no other antigens used; precipitins 1:400; agglutinins 1:100.) Infected same as Control No. 2. Weight 740 grams. Pfeiffer's phenomenon: After 1 hour, few T. B. free, many in leucocytes; after 3 hours, no T. B. free, few T. B. and many granules in leucocytes; after 24 hours, no T. B. free, few granules in leucocytes. Killed 70 days after infection. Weight 735 grams. Autopsy: One nodule in mesentery is all that can be found; it shows fibrous structure with few round cells, no tubercle, no giant cells. Antiformin residue shows one clump fine acid fast granules. Guinea Pig No. 7: Immunized. (The animal's serum shows complement fixation complete with T. B. Emulsion 1:8; neutral fats 1:8; fatty acids 1:8; precipitins 1:400; agglutinins 1:150.) Infected same as Control No. 2. Weight 860 grams. Pfeiffer's phenomenon: After 1 hour, few tubercle bacilli free, many in leucocytes; after 3 hours, no tubercle bacilli free, few T. B. and many granules in leucocytes; after 24 hours, nothing found free, nothing in leucocytes. Killed 70 days after infection. Weight 940 grams. Autopsy: Two small firm nodules in omentum are all that can be found. The slightly larger one shows a fibrous capsule with minute caseous center; smears from this show a few acid fast granules. The other nodule shows fibrous structure throughout.

Group VII.—Fifteen guinea pigs, 14 immunized, 1 normal for control, were infected uniformly with a suspension containing 0.01 milligram of virulent tubercle bacilli by injection with a hypodermic syringe into the lumen of the trachea. Guinea Pig No. 1: Control. Weight 480 grams. Death occurred 23 days after infection. Weight 360 grams. Autopsy: Tuberculosis of axillary and inguinal glands, of peritoneum, liver, spleen, mesenteric and retroperitoneal glands, bronchial glands much enlarged, few tubercle in the lungs. Enlargement and pressure of bronchial glands caused interference with respiration during several days preceding, and no doubt was the cause of comparatively early death. Guinea Pig No. 2: Immunized. Weight 720 grams. (The animal's serum shows complement fixation with T. B. Emulsion 1:4; no other antigens used; precipitins 1:400; agglutinins 1:150.) Killed 8 weeks after infection. Weight 830 grams. Autopsy: Normal findings in all respects, excepting one large gland at bifurcation of trachea. The gland showed a thick, fibrous capsule, centrally round cell, infiltration and a few giant cells. No tubercle bacilli or granules in smears from antiformin residue. Guinea Pig No. 3: Immunized. Weight 820 grams. (The animal's serum shows complement fixation with T. B. Emulsion 1:4; no other antigens used; precipitins 1:400; agglutinins 1:150.) Killed 8 weeks after infection. Weight 850 grams. Autopsy: One enlarged tracheal and one enlarged bronchial gland found to have a fibrous capsule. Caseous centers contain numerous acid fast granules.* Guinea Pig No. 4: Immunized. Weight 900 grams. (The animal's serum shows complement fixation with T. B. Emulsion 1:4; no other antigens used; precipitins 1:800; agglutinins 1:150.) Killed 8 weeks after infection. Weight 880 grams. Autopsy: Nothing found internally. Two enlarged axillary glands show round cell infiltration; no tubercle or giant cells. Smears from antiformin residue show no bacilli, no granules. Guinea Pig No. 5: Immunized. Weight 700 grams. (The animal's serum shows complement fixation with tubercle bacilli emulsion 1:4; no other antigens used; precipitins 1:800; agglutinins 1:150.) Killed 8 weeks after infection. Weight 760 grams. Autopsy: Three enlarged tracheal glands showing round cell infiltration; no tubercle or giant cells. Smears from antiformin residue show few clumps of very fine acid fast granules. Guinea Pig No. 6: Immunized. Weight 640 grams. (The animal's serum shows complement fixation with tubercle bacilli emulsion 1:8; no other antigens used; precipitins 1:400; agglutinins 1:150.) Killed 8 weeks after infection. Weight 760 grams. Autopsy: A slightly enlarged tracheal and a cervical lymph gland, which show round cell infiltration; no tubercle or giant cells. No tubercle bacilli or granules in smears from antiformin residue. Pigs No. 7 to 14 showed complement fixation of 1:4 or 1:8 prior to their infection; they were allowed to live for further observation, as were some others of preceding series, all of which continue in a good state of nutrition and are apparently well.† About thirty rabbits immunized to show results from infection with tubercle bacilli of bovine origin were lost before they were infected in an epidemic of pneumonia.

More numerous experiments with immunized animals would have been made had my efforts to obtain more animals been successful. To compensate for a greater number I have taken extra pains and pre-

*The caseous material was used for subcutaneous infection of a young guinea pig. The animal is living and is growing and increasing in weight ten weeks later. There has been no ulceration of the skin or abscess at the site of infection.

†At the time of proof-reading, August 5, all these animals are still in perfect condition. In other animal experiments completed since May 1 the same results as recorded in this report have been obtained. The serum tests in about sixty additional vaccinations of children and of adults conform in results to those of the present series.

cautions in critical control of their infections and autopsies, and in the maintenance of a maximum degree of virulence of the cultures of tubercle bacilli which were used, which latter is amply shown in the autopsy records of the ten control animals which appear at the head of the several groups of experiments. I may also state in this connection that this present series of animal experiments includes only those made since July, 1911, and that a much greater number of such experiments were made in my preliminary studies of the separate constituents of the preparation during preceding years, the results of which justified me in extending my observations to the human subject for prophylactic purposes. The fact, however, that the blood tests for antibodies, the bacteriolytic action of the immune sera, and the several groups of animal experiments confirm one another and are uniform in correspondence throughout is suggestive that additional animal experiments will not show materially different results. In regard to the preparation itself, I make no claim to the one I have used as being the only one that will cause the results which I have shown. On the contrary, I believe I have made it apparent that any of the constituents of the bodies of tubercle bacilli are more or less effective for the purpose of immunization. What I claim for my own preparation is its safety and its prompt and efficient action to make a single dose effective.

The fact that latent infections are no contraindications to vaccination with a single dose would make a beginning in children having a tuberculous environment particularly feasible and most desirable, since in such families objections to vaccination are not likely to be raised, while the great majority of childhood infections originate among them. The simplicity of the method of giving a hypodermic injection of the liquid without other preparation or examination being required than the exclusion of manifest tuberculous disease and the proper cleansing of the part where the injection is made, makes it particularly available to the busy practitioner, and the inexpensiveness of the necessary dose should bring it within the reach of the poor, for whom, if it be necessary, I shall always be glad to supply it without cost, as far as my laboratory facilities will enable me to comply with such requests.

The employment of this vaccine for therapeutic purposes naturally suggested itself. My studies in this direction indicate that the doses in specific treatment, as practised heretofore, have probably been given too frequently, and that with a preparation like the one under consideration they need not be repeated oftener than once in five days or a week, and that the treatment need not be continued as long as has been the practice heretofore. I likewise find that in early stage cases, especially such in which active symptoms are not present, the initial dose may be much larger without causing marked systemic reactions, and that after three or four doses of 0.05, 0.1, 0.2, and 0.4 c.c. given a week apart an ample degree of immunity can be shown by complement fixation and by the lytic action of the patient's serum upon tubercle bacilli *in vitro*. In more advanced cases longer specific treatment appears necessary, even though ample immunity may be demonstrable, chiefly, I believe, because of the value of focal reactions which cause increased vascular turgescence and permeation of the tuberculous lesions by the patient's own immune serum.

The advanced stages of phthisis do not as a rule offer the best prospects for specific treatment by reason of the caseous and fibro-caseous lesions and suppuration of open surfaces, already present, which are not accessible to the germicidal action of the immune serum. In the more favorable chronic cases in which fever is slight or absent, and the nutrition is still good, I find frequently a fair degree of immunity having developed spontaneously in the course of their disease, and believe that the benefit from further specific treatment in such is then chiefly due to greater vascularity induced by the local reaction after a given dose. This local reaction need not necessarily be dependent upon the use of the specific product of tubercle bacilli, and can be induced by other agents, especially hetol, and this action observed by me for many years during my connection with the Winyah Sanatorium appears to be the true explanation for the favorable observations of Landerer and of others.

Whether or not synthetic chemistry, which has given us material aid in the treatment of syphilis, and is being extended to preparations to be used for carcinoma and tuberculosis, will do more than specific immunization can accomplish the future must decide; but however germicidal such a preparation may prove to be it must depend for its action upon conveyance through the circulation to the point where needed, and must be limited the same as is the bacteriolytic action of the patient's own immune serum, in which the advantage would be in favor of the latter, as if once the patient is immunized the action of his immune serum would be continuous and available for a long period of time, while, as in syphilis, the chemical agent would require more or less frequent repetitions of administration and would leave the door open for reinfection unless the patient has acquired immunity spontaneously or by specific treatment. If, however, the chemical agent would also prove germicidal for other pathogenic organisms, it would be a most valuable aid in treating cases of advanced phthisis with co-existing secondary infection.

These considerations appear to justify all the more my efforts for an effective method of protective vaccination which I believe is the true legitimate field for the employment of the specific products obtainable from the tubercle bacillus, and I venture to claim without fear of successful contradiction that my observations will stand the scrutiny and control of others who are able and have the necessary facilities and to whom I am ready to supply the preparation and any desired further details of technique which I have employed.

The results shown in my bacteriolytic studies *in vitro*, and the evident harmlessness of infections with tube contents in which the tubercle bacilli were more or less disintegrated, would alone establish the fact that the immunity shown in the vaccinated children is of a high degree without further confirmation by the observations of Pfeiffer's phenomenon and the evident protection of immunized animals in that series, against degrees of infection which are never reached under any kind of exposure of the human subject, the changes found in their autopsies, as also those shown after intratracheal infection being similar but much less in extent which I and others have found when dead tubercle bacilli were used in the experiments. I am, however, not unmindful of the advantages that may develop from further studies of the method or of the preparation to be used, which I am myself continuing and in which I hope others will join me. Such co-operation is especially desirable in regard

to the determination of the uniformity of results, when tested upon a much greater number of children, and in their re-examinations from year to year by which it may eventually be shown whether or not latent tuberculous processes are completely eradicated, if revaccination is necessary and when this should be resorted to.

MODERN MEANS OF INVESTIGATING MENTAL PROCESSES.

By WILLIAM J. M. A. MALONEY, M.D., F.R.S., Edin.

NEW YORK.

PROFESSOR OF NERVOUS DISEASES, FORDHAM UNIVERSITY; ADJUNCT PROFESSOR OF NERVOUS DISEASES, POST-GRADUATE MEDICAL SCHOOL; PHYSICIAN IN CHIEF, NEUROLOGICAL HOSPITAL.

A FEW decades ago people were mad only when they were officially committed to institutions for the insane. A man's sanity depended upon his harmlessness to society, and upon the tolerance of his family. Even in those halcyon days the profane convicted our Blessed Lord of paranoia; labeled Julius Cæsar, St. Paul, Mohammed, and Napoleon as epileptics, and therefore, as degenerates; dissected the mind of saint and of genius, and found it perverted, debased, and disordered; unceremoniously hustled the great over the borderland; but left the mediocre complacent that the mad were not they, but the others. Then the comprehensive derogatory terms, neuropath and psychopath, were invented to vex and disturb this serenity. And now, zealous sleuth-like field workers track stigmata so keenly that degeneracy is found to be nearly as prevalent as original sin.

The cause of all the pother is the absence of a standard of sanity. We have no adequate definition of a normal mind. Amongst individuals vast differences of capacity and temperament exist. To the same mental stimulus no two minds yield identical reactions. To the same mental stimulus even the same person never responds twice in exactly the same way. Every mind varies from hour to hour, and this mental change continues always. When stimulated to greater effort, to loquacity, irritability, restlessness, or excitement, we pass through a maniacal phase of mental activity. When weary or listless, dull or sad, we pass through a period of mental depression. In our daily moods we thus enact mildly the cycle of what, when marked, is called manic-depressive insanity. Or if we are inconstant in energy, or fickle of purpose; if in commerce we sigh for journalism; if medicine beckons us from priesthood; if art lures us from law; if we are unsettled and migratory as regards domicile; if we are pedantic in speech, faddists for food, eccentric in dress, precise in manner, or mystical in religion—if we indulge in a chequered career, or a sentimental journey, or Shakespeare's English, or vegetarianism, or non-fashionable attire, or punctilious politeness, or in Buddhism, we show affinities with dementia præcox. Or, again, if we cherish—as we all do in our secret hearts—the conviction of our direct descent from an Irish king, or a pilgrim father, or a Dutch settler; if we fondly imagine we could bankrupt a Morgan, outbuild a McKim, rule a Roosevelt, outsail a Nelson or outmaneuver a Grant; our folly veers toward paranoia. All the morbid phases which we recognize under the magnification of insanity we can detect, as through a reversed telescope, in states of mind which we accept as normal.

Where does the normal end and the morbid begin? Can we determine where idiosyncrasy merges into madness, where eccentricity becomes irrationality, where individualism lapses into lunacy, where pedantry ripens into dementia, or where fanaticism matures to mania? We may regard the average as the normal mental state but we may not regard those who are either above or below the average as necessarily abnormal. Psychologists are still struggling to fix the standards of the average normal mentality of various ages. When these standards are definitely settled, we shall be able to interpret facts concerning an individual's mental processes only upon a basis of personal opinion, and not of knowledge. We shall be able to compare an aberrant individual with the general average, but we shall not know what was that individual's normal mental state, nor what was the amplitude of his normal intellectual variation. We cannot detect slight abnormal changes: and when severe changes occur, we cannot tell how far removed from former behavior the new morbid attitude is. In cases of pronounced aberration our difficulties are merely scientific. Even a jury suspects the sanity of one who seriously claims identity with Cleopatra, a poached egg, or the Prophet Elijah. But upon less bizarre conditions, a Solomon would often need to sit in judgment. Murder has been urgently committed by those who, suspected and confined in institutions for the insane, had just gained a judgment of sanity and freedom from an expert and prejudiced examiner.

The question of the delimination of sanity from insanity, of competency from incompetency, of responsibility from irresponsibility, daily agitates our courts, bewilders our jurists, confuses medical testimony, and embarrasses the expert alienist, as if he were a professional witness. When we are confronted with an individual can we tell about his mental state anything that is not evident to the layman's common sense? What can we do beyond adducing scraps of evidence of the person's intellectual capacity, and offering a comparison with more or less unverified average standards which are alleged to prevail among the citizens of some European town or country? Can we bring forward nothing positive, nothing conclusive, nothing of absolute value?

We have two methods by which absolute knowledge may be gained. The first, the psychoanalytic method, endeavors to resolve the mental state into its fundamental constituents, to disintegrate the existing mental structure. The necessary data for the analysis are obtained from the dreams, reveries, reminiscences, and thoughts of the investigated person together with his reactions to stimulus words. These data are analyzed, correlated, and synthetized. What is obscure is deemed symbolic of erotic imagery. The prevailing content of the person's mind is thus ascertained.

Then by certain postulated mechanisms such as suppression, repression, and conversion, the origin of the content is explained, and its development outlined. The integral portions of the content are neatly labeled according to accepted nomenclature as complexes, and all is now ready for "sublimation" or the proper affective reaction to heal the mental trauma.

The apostle of this alluring method is Sigmund Freud of Vienna. Breuer came before, but he was merely "as the voice of one crying in the wilderness." There is no Freud but Freud. The faithful follow him as the wise men followed the stars.

Freud has taught us that the key to mental processes lies in the study of the evidences of these processes. He has emphasized these evidences, and has given us a method by which to study them. Psychoanalysis may not be a perfect method, but it is the most perfect that we possess. It is indeed our only method, but when we use it in the ancient, stereotyped, slipshod fashion we fortunately do not call it psychoanalysis. Freud sifts the results of his thorough and scientific analysis, and discovers psychic traumata. Doubtless many psychic traumata have a sexual basis. But that all should so arise; that special mechanisms should be invoked so as to procure an inevitable sexual end product; and that every non-organic morbid mental state should evolve from the sphere only of the sexual instinct and not from the other ruling passions—such as gain, self-preservation, etc.—naturally deter many physicians from closely scrutinizing Freud's tenets. Some among these conservatives realize the value of the method, admire the ingenuity, and half believe the truth of a few of Freud's mechanisms. But the disgusting and wild interpretations (interpretations wanting in reason, in decency, and in purpose), which are trumpeted as Freudian by some of his ignorant, self-styled disciples, dissuade them from further inquiries. Up to the present day, Freud has had practically only one adversary—Isserlin. Most other physicians have been either content to ignore or, while more or less acknowledging the value of Freud's methods, to repudiate his inferences and avoid controversy on subjects which naturally offend their susceptibilities. But there are not a few rabid antagonists whose virulent opposition springs from a veritable Freud *Angst*. Their attitude is a blend of the propriety of a schoolgirl with the scurrility of a blackmailer. A Freudianophobe is typically a proper person whose vocabulary, good breeding, and decorum alone limit the expression of his outraged feelings. To him Freud's cases and their marvelous interpretation demand medieval credulity, Freud's wonderful writings are less convincing, less savory, and less familiar than is the Koran to the average Christian, Freud's philosophy is of the madhouse, Freud's methods are a "prostitution of the confessional," Freud's disciples! the lure of the mad is felt only by their kind; and few but the mad herd with the mad. Psychiatrists are always half suspects, and adherents of Freud are but perverted psychiatrists. Freud's cures! Every quack has his cure! and so forth; righteously.

The medical Pharisee obviously differs not a whit from others of his tribe. Seldom has any theory received more abuse and less criticism. Freud has made a serious scientific endeavor to reveal truth, an endeavor which has elicited, not earnest experimental investigation, but ignorant abuse.

The persistent courage and indefatigable ingenuity of Freud no less than the zeal, number, and talents of his followers, merit that his teachings be judiciously considered. If the foolish and merely prurient of the writings of the ignorant Freudians be set aside, and if Freud's doctrines, as enunciated by himself, and by the many distinguished scientists among his adherents be studied, one tithe of the energy spent now in vituperation would settle forever the value of the whole Freud system.

The other method is largely due to Wundt and Emil Kraepelin who with Sommer, Rivers, Hoche, Aschaffenberg, and others have used it to convert psychology into an exact science. In this method all mental processes are measured just as we measure blood-pressure, or visual acuity, or urea excretion.

An individual's capacity for simple mental operations, such as memorizing, counting, choosing, perceiving, associating, etc., is measured. A large number of tests are made so as to ensure that neither freshness, nor fatigue, nor attention, nor boredom, nor practice, nor noviceship will unduly influence the results, and the average of all phases of mental activity will be obtained.

But intellects react differently to the same disease, and the same disease is a variable quantity. No normal except the concerned individual's normal can be used as a reliable standard. So this method has not yet yielded the hoped-for enlightenment. It is, however, eminently suited for the study of normal subjects in whom artificial alteration of the mental state is about to be produced by means of drugs. The person's normal intellectual capacity is determined; the drug—tea, coffee, bromide, or alcohol—is then given, and the departure from the ascertained normal is measured. The method is often modified and curtailed in practice; only one preliminary testing is then done, the drug is administered immediately, and then the mental capacity tests are repeated. Of course, innocuous fluids of similar taste to the alcohol, and other experimental substances, are occasionally substituted unexpectedly, in order to control the results. The value of this work of the Kraepelin school is evident even to the layman and the jurist. If, under the influence of alcohol, a man commits crime, it is nowadays not enough to say that alcohol rendered the man insane at the moment of the crime; the truth of the defense can be tested by direct experiment; alcohol can be given to the prisoner, and the nature of his reaction ascertained. If he show an insane or abnormal reaction, an extenuating circumstance has been established. Further psychological testing may show that in all probability he drank because he was mad, besides being mad because he was drunk.

But this method of psychiatry has narrow limits. We cannot measure the disease process when we do not know the person's normal. We need a certain mental capacity even for the tests. The measurements afford little more than a standard by which to judge improvement.

Knauer and Maloney have endeavored to carry forward this method of investigation. They estimated each other's mental capacity under normal conditions, and then the average mental capacity during artificially induced hallucinatory and delusional states. Alcohol was not used to induce the hallucination because the intoxication was too transient. Morphine induced too great blunting of consciousness. A relatively unknown alkaloid, mescalin, was employed. The normal mental reactions of K. and M. together with all their possible variations were recorded daily for several weeks. Then K. injected M. and studied him for days till the effect passed off. Then M. injected K. Each made four experiments on the other. Then ten doctors successively volunteered and finally six laymen.

The principal effects were hallucinations of vision. Gorgeously colored scenes of marvelous content, and of curiously associated sequence passed almost without ceasing before the eyes. Pictures, palaces, churches, statues, armies of grotesque dolls, animals, etc., rolled past in an incessant panorama of wonderful color. Usually the critique remained—the subject knew the pictures were not real. But

sometimes, as in one case, so disturbingly real were the delusions that the subject had to be restrained from attempting violence upon the French soldiers whom he saw advancing and threatening. Delusions of hearing were rarer and less pronounced. The most curious delusions were those of muscular sense. Limbs apparently disappeared. The body was felt to be cut into separate halves. The head seemed as if replaced by a ground glass screen. The combination of visual and muscular sense delusions produced strange reactions. One person who felt and saw himself to be in dissociated sections tried to dance himself together again.

Control experiments were made with alcohol.

As the mental capacity was ascertained before, during, and after the poisoning as regards power to perceive, to remember, to associate, to differentiate, to calculate, etc., and as the visual acuity, and the muscular sense, were measured, we were able to reach some valuable conclusions as to the mechanism of delusions.

Just as, in alcoholism, subjects are sad or glad, loquacious or silent, combative or peaceful, so in mescalin poisoning the mental state produced varied in different subjects. In all but one case, however, the poisoning seemed to exert a fundamentally similar action. Afterwards, upon reading accounts of opium, hashish, and other narcoses, I was impressed with the essential similarity which characterizes the mental states in all these poisonings. Every account might have been written by the same man about the same drug. When the superficial differences of temperament and capacity disappear in any man, apparently the residue of his mentality shows a common groundwork, a primitive plan and reaction. The same level of mentality can be induced without poisons in spiritualistic mediums, in the hypnotized, and in the hysterical.

Among the sixteen persons tested insanity was present in the immediate relatives of three. The variations of the reactions of these tainted persons was extraordinarily interesting, and gave rise to the hope that further work in this direction might enable physicians to test the offspring of the neuropathic families and classify them according to their mental stability. We would then have an index to the normal, a guide to the abnormal, and a new test of Mendel's law. There is no one so soundly balanced that adequate mental stress cannot unhinge. There are few so weakly ordered that adequate protection cannot safeguard from passing across the dread borderland. If mental stability could be experimentally ascertained, if we could group people, according as average stress means potential lunacy to them or not, and if we could wisely order the education and environment of the easily deranged a great part of the burden of insanity might be lifted from the drooping shoulders of humanity.

20 East Sixty-ninth Street.

Diabetic Eclampsia.—A. Chauffard and H. Rendu state that the demonstration of this condition requires the following data: (1) Anatomical. The absence at autopsy of either cerebral lesions or of old or recent renal changes upon which one might base the origin of a uremic state. (2) Clinical. The exclusion of any possible therapeutic measure that might have caused convulsions (*i.e.* the injection of large doses of alkalies). (3) Chemical. The absence of nitrogen retention and the presence of acetone bodies in the urine or cerebrospinal fluid. The authors report a case of diabetic convulsions occurring in a man, age forty-nine years, in whom the above conditions were fulfilled.—*Revue de Médecine.*

NASAL OBSTRUCTION AS AN EARLY SYMPTOM OF CARDIORENAL DISEASE.*

By WILFRED M. BARTON, M.D.,

WASHINGTON, D. C.

PROFESSOR OF THERAPEUTICS AND PHARMACOLOGY AND ASSOCIATE PROFESSOR OF INTERNAL MEDICINE IN THE MEDICAL DEPARTMENT OF GEORGETOWN UNIVERSITY.

There is considerable literature upon the etiology and pathology of nasal obstruction, most of which is devoted naturally to a discussion of its commoner causes, chief of which are, as is well known, adenoid vegetation, chronic hypertrophic rhinitis, deflections of the nasal septum, spurs, and nasal polypi.

Of the rarer causes of nasal obstruction, of which instances have been reported, the following may be mentioned: congenital malformation; exaggerated prominence of the anterior arch of the cervical vertebræ; facial hyperostoses; symmetrical hypertrophy of the septum; adhesions following scarlatina and variola; myxedema; the use of the actual cautery, etc. I have, however, never seen any reference to chronic nasal obstruction as an early manifestation of cardiorenal disease, and for this reason I have thought it worth while to report the following case which has recently come under my notice, and to follow the same with a brief commentary upon the possible value of the symptom from a diagnostic standpoint: D. R., white, male, aged 79 years. The patient is a very intelligent man and has been in the government service since the Civil War. Family history negative. Has always been physically robust. He has been troubled with nasal obstruction for over twenty years. The difficulty in breathing through the nose was insidious in its onset, and did not follow any acute inflammatory condition. At first and for a long time it was not complete and he could breathe better at times than at others, and one nostril was usually worse than the other. He had no symptoms of catarrh. His work was all indoors and he was not exposed to draughts or cold. About fourteen years ago he noted some dyspnea if he mounted stairs rapidly.

Seven years ago (1905) the obstruction became so complete at times as to cause him great annoyance and he consulted a rhinologist of this city, who proposed an operation to which he readily consented. The operation consisted in an excision of hypertrophic tissue from both nostrils. Immediately after the excision he was relieved of the symptom of obstruction and remained so for about a year or more, when he noticed it began to return and at the end of two years was as bad as before the operation.

I saw the patient for the first time March 23, 1912. About two weeks previously he had been taken sick with terrific retching and coughing during the night, accompanied by expectoration of large amounts of thin, frothy, mucoid sputum. The retching was accompanied by such intense dyspnea that he was forced to sit up in bed to breathe. On account of the nasal obstruction he was forced to breathe largely through his mouth. He noted that his pulse was accelerated and believes that he had slight fever. The attack was accompanied by great diminution of urinary excretion, the color of which was a dark muddy brown.

He attempted to treat himself, taking at first some dilute sulphuric acid, which seemed to aggravate his condition, following this with some lithium

*Read before the Medical Society of Georgetown University, April 13, 1912.

citrate, which appeared to lighten the color of the urine, but did not increase the quantity. The patient noted concomitantly that his legs, feet, and hands were swollen, and that there was puffiness of the skin of the trunk and face, particularly the left side of the face, upon which he was accustomed to lie. He also noted a disagreeable stinging pain over the region of the heart. All of the symptoms tending to become continuously aggravated, he decided to obtain some assistance.

When I saw the patient for the first time, as above stated, March 23, 1912, I found him sitting up in a chair, with a feeble, rapid, and somewhat arrhythmic pulse (130 to the minute). Rapid dyspneic respiration and general edema. Examination of the heart showed the apex beat in the sixth interspace to the left of the nipple line. The impulse was diffuse. There was considerable tremorous epigastric pulsation. The imprint of the stethoscope left a marked ring depression. There was no audible murmur. The first sound at the apex was muffled and faint. The second sound was audible at the apex and markedly accentuated at the base, particularly in the pulmonic area.

Examination of the chest showed moist râles posteriorly and anteriorly. Percussion negative. The skin was pale and edematous everywhere. The left eye was blind from glaucoma and the vision in the right was much diminished from the same disease. An iridectomy had been performed upon the right eye. Bl. Pr. 1035.

Examination of the urine, which was scanty, showed albumin present in slight amount and casts mostly hyaline or partly granular. Sp. gr. 1015; color dark; sediment slight.

The patient was put to bed upon a milk diet and given infusion of digitalis, 5ii, every four hours. Immediately the symptoms amended. The urinary excretion increased in quantity to 5 or 6 pints in twenty-four hours, going down subsequently to 3 or 4. Albumin and casts diminished. The anasarca rapidly disappeared. The orthopnea vanished, as also the retching, expectoration, and precordial pain. The precordial distress kept up, however, until nitroglycerin was given, after which it immediately disappeared. The pulse frequency diminished about 10 beats per day per minute until it had come down from 130 to about 80.

But the fact which particularly attracted the patient's attention was that twenty-four hours after commencing the digitalis the nasal obstruction was relieved and in forty-eight hours it had completely disappeared. He found, as he expressed it, that he could "sleep like a baby" because he could breathe through his nose. So quiet was his respiration that his wife became alarmed when he slept, thinking he might be dead. A rhinoscopic examination showed both nares patulous with plenty of breathing space. The condition has remained unchanged up to the present time.

Cardiovascular Bright's disease, as we usually see it, has a slow and insidious onset. However long before, indeed years before, the typical symptoms appear, the individual may feel one or more of a series of symptoms, which are in themselves apparently trivial, but which, nevertheless, are extremely important from a diagnostic standpoint.

The late Professor Georges Dieulafoy of Paris laid particular stress upon these early signs and designated them under the generic and expressive title of the "little accidents of Brightism." Such symptoms are headache, pollakiuria, polyuria, slight epistaxis, palpitation, cramps in the legs, breathlessness, lumbar pains, ringing in the ears, diminution of hearing and sight, vertigo, itching, tortuous temporal artery, sensation of dead finger (doigt mort), cryesthesia, digestive disturbances. All of these symptoms, or some of them, ephemeral or tenacious, isolated or associated, may appear and disappear for a long time before edema, albuminuria, and cardiac disturbances occur. During the course of this chronic state, intermediate as it were, between sickness and health, accute episodes occur, during which the appearance of acute asthmatic attacks, severe headache and palpitation, digestive disturbances, vomiting, edema, and albuminuria, put the physician upon the track of a correct diagnosis. Such acute episodes are not in reality the beginning of the disease. They have been preceded by months, or even years, by some at least of the "petits accidents du Brightisme."

I have therefore thought in the light of the facts disclosed by the above observation that nasal obstruction may perhaps be worthy of inclusion among what we should rather term the little incidents rather than accidents of Brightism. In my personal case it preceded any other symptom by several years, and was a rather prominent feature of his case. Inquiry disclosed the fact that he had never had any of the symptoms mentioned above under the expression of Dieulafoy, "les petits accidents du Brightisme" except the "doigt mort," and this sign was late in appearing since he did not feel it until the beginning of the acute onset of his disease.

As to the explanation or pathogeny of such a symptom as nasal obstruction regarded in the light of an early manifestation of cardiorenal disease, the most rational theory would seem to be that it is in some way due to insufficient urinary depuration; in other words, to slight or latent uremia, the so-called petite urémie of the French authors.

Upon this hypothesis it might be assumed that in certain individuals in whom the erectile tissues of the nose are in a state of hypersusceptibility the accumulated products of metabolic disassimilation may give rise to a sufficient degree of irritation to produce swelling of the mucous membrane and consequent obstruction of the nose, either as a result of edema of the parts or as a result of vasomotor disturbances set up.

However this may be, I have taken the liberty of reporting this case as a possible contribution to the semiology of cardiovascular disease.

UNUSUAL CONDITIONS SIMULATING APPENDICITIS.

By H. W. EMSHEIMER, M.D.,
NEW YORK.
CHIEF ADMITTING PHYSICIAN, MOUNT SINAI HOSPITAL.

To the average practitioner the diagnosis of a typical case of appendicitis is a comparatively simple matter; the diagnosis of an atypical case or the exact interpretation of an intra-abdominal condition simulating appendicitis is, however, considerably more difficult. While the usual errors in the differential diagnosis of this condition are matters of common knowledge, it is the unusual errors that afford considerable interest and instruction.

Realizing the value of mistakes in diagnosis, I beg leave to cite several of the rarer ones that have come under my observation in the admitting department of Mount Sinai Hospital in the first four months of the year 1912, as follows:

Case I.—*Tuberculous Peritonitis Simulating Appendicitis.*—S. S., age 19 years, male, Italian. Service of Dr. Brill. For five weeks prior to admission patient had had rather constant, moderate pain in umbilical region, radiating to right iliac fossa, to right hypochondrium and to right nipple, with slight fever, but no nausea or vomiting. On examination there was marked rigidity over entire right side of abdomen and moderate tenderness over McBurney's point; no evidence of free fluid; dullness and diminished breathing from angle of scapula to base of lung on right side. There were no other abnormal physical signs. The temperature was 101°; the pulse somewhat accelerated; the blood count showed 6200 white cells and 63 per cent. polymorphonuclears. The diagnosis of an appendicitis with complicating subphrenic or liver abscess was made; but it was decided to place the patient on the medical service for observation. For several weeks the temperature ranged intermittently between normal and 103°; the abdominal signs persisted. Exploratory laparotomy was performed and the entire peritoneum found studded with tubercles.

In this case the diagnosis of tuberculous peritonitis should have been suspected on account of (1) the five weeks' history of constant pain; (2) the absence of localization of pain during this entire period; (3) the absence of leucocytosis; (4) the nationality of the patient.

Case II.—*Henoch's Purpura with Right Iliac Pain, Melaena, and Purpuric Eruption.*—H. S., age 7 years, male. Service of Dr. Koplik. The mother said that the child had had cramps over entire abdomen, especially on the right side, fever and vomiting for three days before admission. Bowels had been constipated, but had moved with enemata, in each case producing, besides the ordinary fluid stool, a small amount of black material. There was moderate rigidity over the lower half of the abdomen, slight tenderness over McBurney's point, and a temperature of 100°; a complex of physical signs which, with the history, had led to the diagnosis of acute appendicitis, for which the child was sent to the hospital. General examination of the child revealed, besides the local signs above described, several swollen joints, around each of which was a group of numerous large petechiæ. Examination of the urine revealed macroscopic blood. Further questioning of the mother brought out the fact that she had noticed the swollen joints and the eruption one day before the abdominal cramps were complained of.

This was a type of Henoch's purpura or of that condition designated by Osler as "visceral crises of the erythema group." An error in this case was avoidable, and due simply to lack of observation; but it serves, however, to bring out very forcibly two general points in diagnosis that have always been emphasized, namely, the necessity of a thorough detailed history and of an exposure and examination of the entire body of a patient, no matter how positive the local signs of a morbid process may be.

Case III.—*Ruptured Hematocele, Symptoms of Recurrent Appendicitis.*—D. S., age 36, female. Service of Dr. Gerster. Patient had had recurrent pains in the right iliac fossa for several months, most pronounced in the ten days before application for admission, some nausea, and occasional vomiting. The last menstruation was nearly four weeks prior to the time of the application. Physical examination revealed slight tenderness low down in the right iliac fossa. The vaginal examination was negative. The diagnosis of chronic appendicitis was made, and the patient placed on the surgical list to await a vacant bed. About three weeks later patient was brought to the hospital suffering from all the symptoms of internal hemorrhage, viz., pallor, rapid pulse, air hunger, etc. A few days after the original examination three weeks before, she had begun to bleed, and had been bleeding intermittently since. Several hours before her second appearance at the hospital she had experienced sudden pain in the right lower quadrant of the abdomen, with the symptoms above mentioned. Immediate laparotomy revealed a ruptured hematocele with abundance of free fluid in the peritoneal cavity.

It is difficult to say whether or not in this case a correct diagnosis was possible at the time of the original examination, especially in the absence of an ectopic history. On this latter account, however, a pelvic examination was probably done perfunctorily, and it is conceivable that a small hematocele might have escaped our examining fingers. This case is cited merely to demonstrate the necessity of making a very thorough pelvic examination in every patient with supposed appendicitis, irrespective of history.

Case IV.—*Plumbism with Right Abdominal Pain.*—W. M., age 48 years, male. Service of Dr. Meyer. Patient, sent to the hospital as a case of acute appendicitis, gave a two days' history of abdominal cramps, especially on the right side, with slight fever and constipation; no nausea, no vomiting, no chills. On examination the entire abdomen was somewhat rigid and tender, especially over the right rectus muscle; no localized tenderness. The temperature was 100, the pulse normal. There were a few blue spots on the patient's chest, apparently produced by paint. Questioning showed that the patient was a painter, and had had several similar previous attacks. He made a quick recovery without operation. Examination of the blood showed no granular degeneration of the red cells nor was lead found in the urine. There was no leucocytosis.

The case is interesting in that it was absolutely impossible to determine whether the patient was really suffering from a catarrhal appendicitis or whether the symptoms were due entirely to plumbism—with the probabilities, however, in favor of the latter.

Case V.—*Appendicular Abscess Simulating Twisted Ovarian Cyst.*—E. K., female, age 13 years. Service of Dr. Brettauer. For one year patient had complained of colicky pains in the lower abdomen, coming in attacks about once a month. Had never menstruated. The last attack, the most severe of any, began five days before admission with severe pain in the lower half of the abdomen, especially on the right side, followed in a few hours by nausea, vomiting, and increased frequency of urination. The pain continued with somewhat diminished intensity to the time of admission. On examination there was slight rigidity and tenderness in the right iliac fossa, particularly just above Poupart's ligament. Rectal examination gave the sensation of a tender, cystic, slightly irregular mass about the size of a plum high up on the right side, and an infantile uterus. The temperature was 100, the pulse 100. An attempt to obtain an ovarian or appendicular Head zone was unsatisfactory. The

diagnosis of twisted ovarian cyst was made. Laparotomy revealed a gangrenous appendix with a pelvic abscess.

Taking into account all the evidence at hand, this error in diagnosis was excusable; in fact, under similar circumstances, the same diagnosis would almost always be made. The only clues that would have been of value in making a proper diagnosis were the slight irregularity of the rectal mass, which pointed toward an acute inflammatory process; and the occurrence of the vomiting several hours after the onset of the pain as distinguished from the immediate vomiting, characteristic of any twist of a pedicle or other structure.

Case VI.—*Septic Non-occluding Thrombus of the Sigmoid Sinus; Streptococcæmia, Appendicectomy, Mastoid Operation, Death.*—F. R., age 17, female. Services of Drs. Lilienthal and Whiting. Eight days before admission there had been general abdominal pain, fever, and vomiting, the pain later having become somewhat localized to the right side. The patient was sent in as an emergency case on account of her supposed abdominal condition. The fact that she had had a discharge from her left ear with perforation of the drum and with fever but no chills was ascertained later. On examination of the abdomen there was rigidity and pain in the right iliac region, where a mass could be felt. There was also a mass in the left iliac region. The white blood count was 19,000, with 82 per cent. polymorphonuclears and with 18 per cent. lymphocytes. The case was recognized to be a doubtful one, but it was thought that a small exploratory opening with appendicectomy could do no harm. The appendix was therefore removed through the usual 2½-inch rectus incision, and at the same time a careful examination of the abdominal and pelvic viscera was made. The wound was closed without drainage. Next day the temperature shot up to 106°. A blood culture was found to be positive for streptococci. Dr. Whiting having examined the left ear decided upon operation, which was accordingly performed in the usual manner. The lateral sinus was exposed and opened and no occluding thrombus but merely a mural exudate was found. The patient died of acute purulent general peritonitis, as disclosed at autopsy six days after her admission to the hospital. Very possibly the general septic peritonitis was determined by the laparotomy in a patient with a positive blood culture. While it is probable that the case would in any event have terminated fatally, it is most distressing to think that an unnecessary laparotomy was performed, and that the abdominal symptoms had so far predominated in the case as to render it possible to overlook the true focus of infection.

The entire account of this case was given to me by Dr. Howard Lilienthal, who has kindly permitted me to make use of it in this paper instead of reporting it himself, as was his original intention.

Case VII.—*Retroperitoneal Lymphosarcoma, Simulating Acute Appendicitis.*—I. R., age 30 years, male. Service of Dr. Lilienthal. For six months patient had complained of burning pain in epigastrium, and nausea. For three days had pain in both iliac fossæ, occasional vomiting, and moderate fever. On examination patient had moderate tenderness and rigidity in right iliac fossa, not particularly over McBurney's point. Temperature was 102°, pulse 110. At operation, which was done immediately with the idea that a gangrenous appendix would be found, the latter was seen to be absolutely normal. With the exception of a small soft movable mass in the mesentery, thought to be inflammatory in nature, there were no signs of any intra-abdominal abnormality. After operation patient began to have peculiarly remittent and intermittent fever, for which no cause could be ascertained. Emaciation became marked, and patient seemed to be losing ground rapidly. The abdominal pain continued with somewhat increasing intensity, and so about one month after the original operation a second exploratory laparotomy was done, resulting in the discovery of a large inoperable retroperitoneal growth, probably sarcoma.

This is one of those cases where, unfortunately, our methods of clinical examination are not sufficient to permit of a correct diagnosis, and where exploratory laparotomy is absolutely necessary to clear up the situation.

Case VIII.—*Appendicular Abscess, Endocarditis, Suspected Mesenteric Thrombosis.*—R. W., age 19 years, female. Service of Dr. Rudisch. Patient gave a distinct past history of rheumatism and endocarditis. One year before had general abdominal and right iliac cramps lasting for three days. Eleven days previous to admission complained of fever and symptoms of beginning cardiac decompensation. Four days before admission began to have general abdominal pains, very severe in character, especially in the right iliac fossa; vomited several times at onset. On examination there were signs of slightly decompensated mitral and aortic disease; tenderness and rigidity in both iliac fossæ; a temperature of 101.6° and a pulse of 88. By rectum there was a distinct tender bulging mass high up on the right side. The blood count showed 22,000 white cells, 80 per cent. polymorphonuclears. Patient was sent to the hospital with the diagnosis of a suspected mesenteric thrombosis, but in the absence of bloody stools, and the presence of a high blood count and a rectal mass, the diagnosis of appendicular abscess was made, and proved correct at operation.

Here it was impossible to explain the physical signs according to the usual rule of supposing a single etiological factor, inasmuch as there were unmistakable evidences of a second, entirely different process at work.

Case IX.—*Tuberculous Peritonitis, Sudden Onset and All Signs of Acute Appendicitis.*—M. C., age 25, Irish, female. Service of Dr. Lilienthal. For six months patient had been subject to moderate, rather constant abdominal pains. Twenty-four hours before admission had sudden pain in right iliac fossa, with fever, nausea, and vomiting. There was rigidity in right lower quadrant of abdomen, with marked tenderness over McBurney's point. Temperature, pulse, local signs, and general appearance of the patient pointed unmistakably to the diagnosis of gangrenous appendicitis. At operation the entire parietal and visceral peritoneum, especially right tube and appendix, were covered with miliary tubercles.

Here again a proper diagnosis was impossible. The above clinical picture, however, with acute onset and signs of a general peritonitis is not so very rare in tuberculous peritonitis. It is instructive to note that in the two cases of tuberculous peritonitis mentioned in this paper, and selected at random, the patients belonged to the nationalities reputed to be among the most susceptible to tuberculosis—Italian and Irish. This is a rather significant fact and should put us on our guard when-

ever we are dealing with indefinite abdominal signs in patients of the nationalities above stated.

Case X.—*Intra-abdominal Actinomycosis, Seven Months After Appendix Operation.*—R. B., female, age 17 years. Service of Dr. Gerster. Seven months before admission patient had an operation performed for acute appendicitis. With the exception of occasional pain in the right lower abdomen, was well since operation up to two weeks before admission, at which time she began to complain of pain in the right hip and right iliac fossa, especially on walking, so severe that for several days patient had been confined to bed. Moderate fever; no chills or vomiting. Physical examination showed a large, hard, tender mass the size of a grapefruit in the right iliac fossa, apparently extending into the pelvis. Patient held thigh flexed on hip. The diagnosis of postoperative intra-abdominal abscess was made in the admitting room. Laparotomy revealed a huge abscess, a culture of which contained actinomyces.

Although rare, actinomycosis should be considered in all cases of chronic abscess or chronic inflammation; but a positive diagnosis, especially if a causal factor cannot be determined, is extremely difficult.

Case XI.—*Multiple Liver Abscesses Following Undiagnosed Appendicitis.*—L. K., age 28, male. Services of Drs. Meyer and Lilienthal. Patient had had ten similar previous attacks in the last thirteen years. For two weeks had had abdominal cramps, especially in the epigastrium, with occasional vomiting. There was rigidity of the upper rectus muscle, more on the right side, marked right subcostal tenderness, a high blood count, and fever. Patient had repeated chills and an intermittent septic temperature. At operation the appendix was found much inflamed and enlarged. A portion of mesentery and of liver were excised for macroscopical examination. The pathologist, Dr. Mandlebaum reported diffuse acute inflammation of appendix and mesentery, with purulent thrombosis of mesenteric vessels and multiple purulent foci in liver.

The last case has been cited to illustrate the disastrous consequences of undiagnosed appendicitis, and the necessity for prompt surgical intervention in any case where appendicitis is suspected.

Case XII.—*Lobar Pneumonia, with Referred Appendicular Pain.*—R. G., age 13, female. Services of Dr. Koplik and Dr. Manges. For five years patient had had abdominal cramps and nausea. For three days pain had been most severe in right iliac fossa. Vomited twice at onset. No other symptoms. Patient was sent to the hospital with the diagnosis of appendicitis. There was slight tenderness in the right iliac region; otherwise the abdominal examination was negative. Examination of the chest showed a small area of bronchial breathing and râles at left base. Temperature 100.6°, respirations 26. No operation was performed. In twenty-four hours the pulmonary signs were unmistakable, and in a brief period the pneumonia was in "full bloom."

These twelve cases serve to illustrate the truth of the assertion that the diagnosis of an atypical case of appendicitis, or of an intra-abdominal condition simulating appendicitis, is not easy, and emphasize very forcibly the necessity in all cases of doubtful diagnosis of a most careful history and a most painstaking physical examination. It is by these means only that we can hope to avoid disagreeable surprises and to progress in the clinical diagnosis of intra-abdominal conditions.

I am indebted to the superintendent and attending physicians and surgeons of Mount Sinai Hospital for the use of the various hospital records necessary for the preparation of this paper, and to Dr. Harold Neuhof for several valuable suggestions.

THE TREATMENT OF PUERPERAL ECLAMPSIA.*

By ROBERT E. COUGHLIN, M.D.,

BROOKLYN, N. Y.,

CONSULTING PHYSICIAN TO THE BAY RIDGE SANITARIUM; ASSISTANT PHYSICIAN TO THE NORWEGIAN HOSPITAL; VISITING PHYSICIAN TO THE BAY RIDGE HOSPITAL AND DISPENSARY.

Bar has made a careful study of the causes of puerperal eclampsia and has arrived at the conclusion that the cause is a complex toxemia. The nature of the primary poisons is unknown. Their action causes secondary poisoning of the kidneys and liver, and the poisons thus produced add to those already acting and cause the preeclamptic state. Hypertension, although the immediate cause of the attacks, is not the primary causative factor. Thus there is a complex condition of toxemia of the blood serum, acting on the liver, kidneys and brain, resulting in the phenomenon which is called puerperal eclampsia.

Probably no originality can be claimed for the statements regarding the treatment of convulsions in pregnancy as outlined in this paper.

In 1889 Love published an article in which he claimed that Dr. Newton twenty-five years before managed cases of puerperal eclampsia by administering large doses of veratrum viride. Fordyce Barker had prior to this time written about the drug in peritonitis and phlebitis. Later than 1889 obstetricians like Barrows, Edgar, Chandler, Willis, Grindell, and others have testified to the efficiency and efficacy of veratrum viride in eclampsia. However, in these times of therapeutic nihilists, doubters, and worldly-wise men it may not be amiss to state the facts to date concerning one very useful drug in our materia medica. On this account it does not appear to be necessary to offer an apology for going over old ground which has already been well covered in the past.

The treatment of puerperal eclampsia in private practice and at the Norwegian Hospital as advocated by the writer resolves itself into conservative means at the outset with heroic methods at a later period. As soon as a patient is admitted in convulsions with high blood-pressure and rapid pulse she is put on the tincture of veratrum viride in fifteen minim doses every fifteen minutes hypodermatically until the pulse shows signs of slowing up perceptibly or the convulsions have discontinued. As a rule, when the pulse has been brought down near the normal rate the convulsions are controlled. At this time observation will show that the pulse has not only become slower, but softer in character. Along with this condition of affairs the blood-pressure has been markedly reduced. At this time the drug may either be discontinued absolutely or given in much smaller doses at infrequent intervals, viz., five minims every four hours. A certain time is allowed to go on (from four to six hours) from the time of the last convulsive seizure when steps are taken to bring on labor. This delay is considered

*Read before the Long Island Medical Society, Dec. 5, 1911.

wise as veratrum viride combined with emptying of the uterus may together produce fatal shock. Rapid emptying of the uterus in eclampsia frequently causes a decrease in blood-pressure amounting to 100 mm. Hg, and causes collapse or shock. Veratrum viride given to its full physiological effect may cause a drop of 145 mm. of Hg and produce shock. It seems better for these reasons to allow the system to recover fairly well from the shock of the drug before rapid emptying of the uterus is employed.

No matter what the period of uterogestation, the bringing about of labor is indicated, the idea always being kept in mind that the longer the patient is left in a condition of toxemia of the convulsive type tendency, the slighter are her chances for life with each convulsion. Likewise the child, for the more convulsions the greater are the risks to the life of the fetus. Labor is induced by means of the catheter and forcible dilatation. Once there is full dilatation the delivery is accomplished as rapidly as possible, instruments being used if the progress shows a tendency to be slow.

The anesthetic used is either chloroform or ether preceded by a hypodermic injection of morphine, one-eighth of a grain. Ether does not cause as much kidney congestion as chloroform and appears to be the safer anesthetic, though there is more trouble in getting a patient under ether than there is in chloroform anesthesia.

To relieve the condition of the kidney diuretin and potassium citrate are the diuretics employed. Aconite is also given at times for its diuretic action. Ten-gallon rectal irrigations of normal saline solution are also employed along with a retaining rectal injection of about four ounces. Cathartics are given and the patient is kept in a hot pack. For failing heart conditions consequent upon the toxemia we have to fall back on strychnine, tincture of strophanthus and whiskey. For extreme nervousness bromide of sodium is given in almost all cases. The diet consists of milk diluted in different forms, cereals, gruels, toast, oatmeal jelly, rice, and prepared buttermilk.

In desperate cases or when there is pulmonary edema atropine sulphate in one seventy-fifth grain doses is administered hypodermatically. Case reports of the following successive cases will illustrate the treatment which is generally successful.

Case I.—Mrs. Emma R., age 41, housewife, U. S., primipara; admitted April 14, 1911. Discharged May 5, 1911. A stout, well-nourished woman. Had been married six years. Never had a miscarriage or been pregnant up to the present pregnancy. Last menstruation June 26, 1910. Examination showed that the external os was dilated about three fingers and fairly soft. Buttock and anus of child felt, also sacrum and coccyx in the L.S.A. position.

The history of the case showed that she had been in labor for a period of twelve hours and had had two severe convulsive seizures. Pulse ranged from 110 to 120. Blood pressure 235 mm. of mercury. Pulse very hard and wiry to the touch. Treatment: High retaining injection of normal saline solution four ounces in quantity. Hot packs were administered every two hours. Tincture of veratrum viride given by mouth every fifteen minutes till she had in all 675 minims, covering a period of twenty-three hours. By this time the blood-pressure had been reduced, the pulse slowed down to 68 and was fairly soft. Three hours later the os was forcibly dilated and a dead fetus was delivered with the breech presenting. After the birth of the child the veratrum was continued in the same manner till 75 more minims were administered, making in all 750 minims in a little over twenty-four hours. The remainder of the treatment was expectant and the patient made an uneventful recovery.

Case II.—Mrs. Ada O., age 35 years, U. S.; admitted to hospital October 24, 1911. Discharged November 16, 1911. Was admitted in an unconscious condition. Objective symptoms: stertorous breathing, frothing from mouth, cold, clammy skin, moderately dilated pupils, extreme restlessness, pulse 124 full and bounding, cyanosis present, some dilatation of cervix, and an excessive amount of albumin in the urine.

Previous history: Has had three children, the present being her fourth pregnancy. During the first pregnancy she had albuminuria, but no eclamptic seizures. Family history was negative, except that her father died of apoplexy in his forty-second year and one sister has chronic kidney disease.

History of present illness: Two months ago while in the country she was seized with a violent headache with vomiting. A country physician was called in and she was advised by him to put herself in the hands of her physician in the city as soon as possible. He examined the urine, but did not tell her the result of the analysis. She returned to Brooklyn, but failed to follow instructions. While on the train to her home she had some dizziness and vomiting, but this had always been her habit when traveling. After returning home she became better and none of her friends apparently realized the seriousness of her condition till she was suddenly seized with a convulsion while asleep in bed.

Examination on admission: Heart impulse of medium force, pulse tension high; no adventitious sounds present. Urine passed involuntarily.

Treatment: Tincture of veratrum viride in fifteen minim doses hypodermatically every fifteen minutes. In twelve hours seven drams had been administered, when all convulsions ceased. Hot packs were also used and four-ounce rectal saline injections were administered every four hours. Tincture of strophanthus and caffeine were given after the veratrum was discontinued because of the weak heart action and condition of the pulse. In all there had been thirty convulsions. Eighteen hours after the patient's admission a catheter was inserted into the cervix and uterus. Five hours subsequently forcible dilatation was instituted and a live child was born in half an hour by the aid of forceps.

Nothing eventful occurred in the subsequent recovery of the patient, who left the hospital in three weeks, except that the uranalysis showed a trace of albumin with a specific gravity of 1010.

Case III.—Mrs. W., age 38, housewife. Was admitted to hospital November 23, 1911. Family history negative. Multipara, the present being her fourth pregnancy. No history of previous kidney disease could be obtained. Patient gave birth to twins eight hours prior to admission to hospital. Seven hours after delivery convulsions set in, five or six occurring within an hour. After admission the convulsive seizures were almost continuous.

Condition on admission: Coma present, though she could swallow fluids; both eyeballs rotated downward, pupils equal and reacted to light. Pulse from 110 to 120, temp. 99.5°, tension and blood-pressure very high.

Uranalysis: Color, not clear; reaction, acid; albumin, a very large amount; no sugar; flocculent deposit; few leucocytes; granular and hyaline casts.

Treatment.—She was put on hot packs every four hours and tincture of veratrum viride given by mouth, fifteen minims every fifteen minutes. Rectal injection of normal saline solution four ounces, to be retained, every four hours. During a period of ten hours she was given 625 minims of the tincture of veratrum viride when it was discontinued, the pulse being around 70 per minute by this time soft in character. Stimulants were now given. Caffeine two grains, strychnine sulphate one sixtieth grain and tincture of strophanthus three minims every four hours. For over twenty-four hours her condition, though she was comatose, appeared to be good. Later while in a hot pack the pulse suddenly went up to 120 and her heart stopped beating. Her respirations continued for a time, but she could not be resusitated. Everything pointed to the severe toxemia of the disease having caused death, for she had not received any veratrum viride in over twenty-four hours. This case illustrates very well how uncertain and how serious eclampsia really is, even after the uterus has been emptied and the convulsions have been controlled.

Conclusions.—Veratrum viride is a very important drug in the treatment of convulsions due to the toxemia of pregnancy. It acts best when given in large doses at frequent intervals. It may be administered either by hypodermic injection or by the mouth, but the former method is preferable because of a better and more prompt action.

Veratrum viride lowers the pulse rate by direct action on the muscle and by stimulating the inhibitory nerves of the heart. It reduces spinal action, also arterial action, and is said by Wood to be the safest of all cardiac depressants. Instances are on record in which a dram of the fluid extract has been taken without fatal results, also a tumblerful of the tincture. Either the tincture or the fluid extract may be administered, the latter being twice the strength of the former.

It should always be given till its physiological action is produced, viz., slowing of the pulse. When this has been accomplished the convulsions will have ceased.

When the convulsions are under control and there is a little improvement in the general circulatory system, as will occur when the convulsions have ceased, a rapid delivery is the next step. After the uterus has been emptied and the convulsions are in abeyance we should expect improvement in metabolism, in the circulation by a reduction of the blood-pressure, in the condition of the urine, in the temperature, pulse, respiration, saving the heart and the cardiac muscle from unnecessary strain, and generally increased elimination.

428 Forty-seventh Street.

REMOVAL OF ADENOIDS AS A PREVENTIVE MEASURE AFTER EXPOSURE TO MEASLES.

By JOSEPH B. GREENE, M.D.,
ASHEVILLE, N. C.

Preventive medicine is now the order of the day, and in no branch of the science of medicine is this more important than in otology. We are every day confronted with adhesive processes resulting from an inflammatory condition of the middle ear which baffles our efforts to restore the hearing to anything approaching normal. It is certainly easier to prevent deafness than to cure it.

Inflammatory processes of the middle ear which result in suppuration are not without danger to life, particularly so when extension takes place to adjacent parts, as the mastoid cells, the lateral sinus, or brain. According to Borden in the *Boston Medical and Surgical Journal*, July 15, 1909, middle ear involvement is more frequent in measles than any other acute infectious disease, though some authorities place scarlet fever first and measles second. Appreciating the great danger of a suppurative ear complicating measles in the presence of a large adenoid is my reason for reporting the following case:

Patient R. S., age 5, was referred to me on March 1, 1912, for defective hearing—no fever—no earache. There was a history of symptoms of the presence of troublesome adenoids, such as mouth-breathing, earache, and frequent colds in the head. Examination confirmed the presence of large adenoids. The ear-drums were red and slightly swollen. Hearing was very defective as evidenced from conversation. No accurate hearing tests could be made on account of the age of the child. Treatment by gentle inflation and mild applications to the nose and nasopharynx had little effect on the hearing. On March 11 the patient was exposed to measles from sleeping with his little sister, who suddenly broke out with a rash and the usual symptoms of this disease. Dreading the effect of an attack of measles on my little patient's already subacutely inflamed ears (in the presence of large adenoids), I advised the removal of the latter. I felt reasonably sure that we had seven or eight days for the nasopharynx to heal before the patient was likely to come down with measles. In this estimate of time we were not disappointed, for eight days after operation the catarrhal symptoms of measles appeared. The ear condition was not made worse by the disease, and at no time did he complain of earache. As soon as the symptoms of measles had subsided the condition of the ears as evidenced by the appearance of the drum membranes and the hearing began to improve rapidly. The hearing continued to improve till it was apparently normal.

While not advising adenoid removal as routine after all cases of exposure to measles, it does seem to me that there are cases where surgical intervention becomes conservative treatment.

Multiple Arthritis of Doubtful Origin.—D. C. L. Fitzwilliams reports the case of a girl, aged fifteen, with the following history. About eighteen months ago the tarsal joints became painful and swollen, first the right and then the left. About four months later the wrists became affected, the left first. The condition has steadily become worse, the pain has remained, but varies from time to time, while the movements of the affected joints have become very limited. Present condition: The patient limps on walking, owing to the pain in the tarsal joints of the right foot; the ankle joints are free. She has pains at night both in the foot and in the wrists. Both wrists are flexed, the left one having no movement at all, while the right one has very slight movement. The synovial membrane of the joints is thickened and the interphalangeal joints of the hands are distended with fluid; there has been no abscess formation. The heart, lungs, liver, and spleen are normal, and there are no enlarged glands. No history or evidence of syphilis. The treatment hitherto has been carried out apparently under the impression that the condition is tuberculous, for the wrists have been in plaster of Paris for three months. *X*-rays show very little bony change in the wrists. The condition is thought to be due to a chronic infection and not to tubercle.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

New York, August 31, 1912.

THE PERSISTENCE OF CERTAIN RACIAL CHARACTERISTICS.

UNDER the above caption, Pearce Kintzing, in our issue of August 10, 1912, discusses in detail the various signs by which one may be able to recognize the presence of negro blood in a person whose parentage is of doubtful origin. He draws attention to the peculiar distribution of pigment around the genitalia, the nape of the neck, and all other parts of the body where even the white man of pure blood has an excess of color. He likewise discusses at great length the peculiarity of the finger nails of persons who may show no other signs of negro blood. This consists essentially of the absence of "half moons," which is generally characteristic of persons whose blood is attenuated by a negro strain. After much careful study of the subject and long actual observation, the author comes to the conclusion that there is no positive sign whereby a very much diluted strain of negro blood may be discovered. This is contrary to the prevalent idea that the offspring of even the most attenuated mulatto and a pure white always has some trait which reveals itself to the expert. The conclusions of this clinical observer are, however, in exact keeping with the most advanced knowledge on the subject of heredity as given to us by students of Mendelism and Eugenics.

Thus Davenport, in his work, "Heredity in Relation to Eugenics," states that the pigmentation of the skin of the child is never, or, at least, very rarely darker than that of the darker parent. In the same manner Karl Pearson, a number of years ago, caused an investigation to be made into the skin coloor of the mulattoes and sambos of the British West Indies. His investigations were published under the auspices of the school of biometricians of which Sir Francis Galton was the illustrious founder, and they tended to discredit the superstition that there was always the danger of a "throw back" to a pure black type whenever either parent had the slightest trace of negro blood in his veins. In fact, Pearson was unable to find a single well authenticated instance of this kind, and, therefore, came to the conclusion that when such a thing occurred it was due to the fact that the child's parentage had in reality not been that which was commonly supposed. Every investigation goes to show that skin coloration, and indeed all the negro physical characteristics, will be eliminated by frequent crossings with white stock, and give place in time to those of the white race.

In this connection it is interesting to note that the old laws and customs of the French West Indies anticipated the scientific conclusions of the latter day observers and students of heredity. According to Kitty Montrose, in the *New York Times*, June 3, 1910, there was an exact legal definition of white and colored. No white could be held as a slave and the exact proportion of negro blood was defined which served to make the man fall into the negro classification. The law was as follows:

White and negro, mulatto, ½ black.
White and mulatto, quadroon, ¼ black.
White and quadroon, octoroon, ⅛ black.
White and octoroon, quinteroon, 1/16 black.
White and quinteroon, griffada, 1/32 black.
White and griffada, mustafee, 1/64 black.
White and mustafee, mustee, 1/128 black.
White and mustee, sang d'or, 1/256 black.
White and sang d'or, white again, not a negro, and could not be held as a slave.

We call attention to this remarkable coincidence of legal conclusions in the West Indies a hundred years ago, with those of the modern students of heredity, because it is interesting to note the difference between popular belief on this subject in that region and in the United States. Here the probability of a "throw back" has always been used as a strong argument to deter mixed marriages of any degree. There the improbability of such an occurrence was not only popularly but legally recognized. Perhaps the explanation of such different beliefs is to be found in the great abhorrence with which such unions have been regarded in this country. It is entirely conceivable that the strong inborn repugnance of the Anglo-Saxon and Teutonic settlers of this country to the race as contrasted to the easier way of looking at the subject, maintained by the Latin races of the West Indies, would suffice to make the former prejudiced observers. Another explanation may be that the Puritan hypocrisy of our own people has made them refuse to admit an illegal and or more or less disgraceful parentage for the child which was darker than it should by rights have been. At any rate the whole subject is interesting to the student of human nataure in its moral and social attributes as well as to the student of heredity and eugenics.

"DIATHESIS" IN GERMAN MEDICINE.

THE lukewarm attitude, often carried to open hostility, of the German medical savants of a generation ago towards the diathetic interpretation of the phenomena of disease by French and English practitioners is probably not fully realized to-day. With the advent of the germ theory the diathesis idea was temporarily side-tracked, so that the present generation has grown up largely in ignorance of the old controversies. It knows that there are certain predispositions which make tissues a superior culture medium for germs of various kinds. It also knows that certain anomalies of metabolisms are regarded

as actual diseases and not simply as conditions which invite disease. Hence the conceptions of diathesis has become in part superseded through the natural march of scientific discoveries.

It therefore appears most singular that while other countries, including France and Great Britain, have been writing less and less of diathesis, Germany should be the one to rehabilitate the idea. The pathologists of Germany and Austria never denied the existence of a predisposition to constitutional diseases, but when it came to giving all the ear marks of several diatheses, as well as the method of their operation, such doctrine was placed perilously near pseudo science—near phrenology, for example.

At a recent session of the Aerztlicher Verein in Nürnberg (*Muenchener medizinische Wochenschrift*, July 30) Kaspar traces the history of the new diathetic teaching in Germany. It appears that Comby, the French pediatrist, in 1900, postulated the existence of a single infantile diathesis which predisposed to the greater portion of chronic infantile morbidity. A single diathesis is evidently a great improvement over half a dozen with hair-splitting, imaginary distinctions and the connection of this diathesis with tender years made it possible to trace its presence during the maturity and old age of the subject. But out of Comby's one diathesis the German pediatrists have made at least two, viz., the spasmophilic and exudative, which, however, may readily coexist in one individual. The exudative diathesis of Czerny has made good in medicine, Kaspar states. He has shown that with the most faithful care certain children develop "milk crust" on the scalp and face (the adjective "exudative" is based on this phenomenon) and that a little later the same children have their anginas and false croups, enlarged tonsils and adenoids. These children are not rendered secure by breast milk and go from one ailment to another. They make up much of the pedatrophy class. They bear badly measles and vaccination. Scrofula is the exudative diathesis plus the action of the tubercle bacillus. As to the nature of this condition Czerny believes it due to defective metabolism of fat. The way to proceed against it is summed up in two words—proper diet. These children do best by cutting out fat as far as possible and making free use of carbohydrates. The diet is almost vegetarian. Even milk and eggs are forbidden. Upon this diet the improvement is striking. The resistance to disease and general appearance promptly improve. While the condition described is not new the treatment is radically novel.

THE SYNDROME OF ACUTE DEHYDRATION IN DIABETIC COMA.

A special syndrome whose elements have been separately recognized as part of the clinical picture of diabetic coma, but whose causation is given a new interpretation, is described by A. Chauffard and H. Rendu (*Revue de Médecine*, June 10, 1912). An acute dehydration of the organism is regarded by these observers as largely responsible for the production of this syndrome. The most striking of its manifestations is the facies of the patient; the cheeks are hollow, the eyes are sunken, and the lines of the features are drawn. This appearance is suggestive of the characteristic facies of cholera, but differs from the latter in the presence of the rosy or cyanotic coloration of the skin which is not present in cholera except during the stage of congestive reaction. There is also noted as part of the dehydration syndrome of diabetic coma a typical condition of the integument, which is flaccid, hypotonic, and devoid of suppleness or elasticity, and which by the appearance of covering the body too loosely has received the name of "batrachian skin." Another characteristic of this condition is the arterial hypotension. In addition there is the ocular hypotonia described in 1904 by Krause: the eyeball appears withered as if half emptied of its contents. Examination of the blood shows increased viscosity, and urinary analysis reveals a nitrogen retention.

In interpreting the mode of causation of this syndrome the authors believe that the following sequence occurs: The diabetic becomes first comatose, and dehydration follows as a secondary manifestation. This results partly from the vomiting, the diarrhea, and the polyuria. These are, however, only contingent factors. The fundamental cause of dehydration is the striking symptom known as Kussmaul's respiration. This form of breathing, which is in reality a polypnea rather than a dyspnea, is an habitual accompaniment of diabetic coma. The patient breathes at the rate of twenty-five to forty times per minute for a period of from twenty-four to forty-eight hours preceding death. The amplitude of the respirations is no less than normal, and the pulmonary ventilation is consequently more active than in the healthy subject. This causes by way of the lungs an enormous increase in the loss of water to the organism, so that of all forms of coma, that occurring in diabetes is the most dehydrating.

As a practical conclusion based upon their observations the authors suggest a new principle in the treatment of diabetic coma. This treatment should be directed against the dehydration and the increased viscosity of the blood. Instead of the administration of concentrated solutions of alkalies the authors advocate the employment of isotonic solutions titrated to the extent of fifteen to twenty grams per liter. By means of an intravenous infusion of one liter of such a solution one may counteract the dehydration of the tissues. In this manner both the mechanical and the chemical indications in diabetic coma are successfully met.

THE ACUTE SHEDDING OF HAIR IN CIRCULATORY DISORDERS.

The cause for rapid loss of hair of the scalp is to a very large extent unknown. The phenomenon is in most instances connected with a serious condition of health, but as yet no one has been able to point out with certitude what particular part of the system is in fault. In diabetes hair is apt to fall out and in cancer this is commonly the case. Of course in a large number of cases of premature baldness, some local affection such as sebor-

rhea is the cause, but where local agencies are absent, the matter must be explained in some other way. David Walsh discussed this question in the *Medical Press and Circular*, July 24, 1912. He holds that constipation exerts a powerful predisposing or exciting element in the shedding of hair. But if so, the toxic theory does not cover the whole ground; and Walsh thinks that more power is attributed to the positive mischief caused by the blood than it is entitled to. May not the damaged nutrition of the hair follicle and the hair bulb result from a lessened or interrupted local circulation? According to Walsh the viscous circle which is set up in the acute alopecia is somewhat as follows: The bowel toxins enter into the general circulation, where they give rise to anemia and eventually to the feeble circulation associated with chronic constipation, probably arising ultimately from weakening of the heart muscle. The result is shown in the peripheral circulation and naturally enough in the hair follicles and bulbs, which represent some of the finest, if not the finest capillary endings. The sudden stoppage of nutrition is quickly registered in the dry and shrunken hair bulb, which is ready to fall out from the follicle with little or no provocation. Or if it be retained for a time by reason of its mechanical interlocking in the upper part of the hair follicle, the failure of nutrition is shown by the changes in the hair shaft which becomes dry, brittle, and often split at the ends.

The chain of events is probably as follows: The bowel produces the toxin, which by reason of stagnation of the bowel contents, is absorbed into the blood stream; the heart muscle undergoes more or less degeneration, following upon the secondary anemia and direct and indirect toxic action; the surface circulation suffers, and with it the vascular supply to the hair follicles. The hairs shrivel and die in consequence. It is a fact of common observation that many of the acute fevers are attended or followed by a rapid and extensive loss of hair. In this sequence of events, in Walsh's opinion, the primary organ in fault is most probably the heart, the muscle of which has been weakened by the high temperature and by toxic fever products.

The United States Public Health Service.

In former issues we several times called attention to the so-called Personnel Bill designed to make the salaries of the officers of the Public Health and Marine Hospital Service equal to those of the corresponding grades of the army and navy medical services, and urged its passage by Congress. The original Personnel Bill had passed the Senate and with a favorable report from the Committee on Interstate and Foreign Commerce was awaiting action by the House. On August 13, 1912, the bill was taken up by the House and amended by substituting for the original a bill offered by Mr. Mann. The amended bill passed the House and Senate on that date and was approved by the President on August 14. The bill as passed contained the essential features of the original with certain additions. The name of the service is changed from the Public Health and Marine-Hospital Service to the Public Health Service, a title at once shorter and more usable. The salaries of the officers are made equal to those of the medical corps of the Army and Navy. Provision is made for the service to investigate the "diseases of man" and the conditions influencing their propagation and spread. This is to include sanitation and sewage, as well as the pollution, both direct and indirect, of the navigable streams and lakes of the United States. It is also provided that from time to time the Public Health Service may issue publications containing information for the use of the public. Congress has done well to pass this legislation, not only as a matter of justice to the officers of the Public Health Service and recognition of the splendid work of the Service in the past, but also as a necessary step toward insuring the continuance of this efficiency. Under the admirable leadership of Surgeon-General Blue it is not too little to expect a great advance in the value of its Public Health Service to the nation, in preventing and controlling disease, especially epidemic disease, among human beings. When a Department of Public Health is created, as it undoubtedly will be in the near future, there will be little to do to make it effective beyond the transfer of cerain bureaus from other departments to the Public Health Service and the elevation of that to the dignity of a department already in full working order.

Significance of Chvostek's Sign in Older Children.

This sign, which consists in a sudden contracting of the muscles supplied by the facial nerve as the result of percussion over this nerve at a point midway between the zygoma and the angle of the mouth, has been regarded as pathognomonic of tetany. On the other hand, many competent observers have noted that the facialis phenomenon is frequently present in nervous children. Among these observers may be mentioned Frankl-Hochwart, Loos, Herbst, Sperk, and Hochsinger. A further contribution to this subject is made by M. H. Bass (*American Journal of the Medical Sciences*, July, 1912), who examined with reference to this sign, 495 children brought to the dispensary for various conditions. He found that the sign was positive in 3.2 per cent. of these cases. The sign was present in 1 per cent. of the children under 3 years, and increased in frequency with the increasing age of the child after this period, until the percentage of 19.6 was reached in children from 10 to 14 years of age. On the basis of the fact that in America tetany is relatively an uncommon disease, Bass concludes that the above figures furnish additional evidence that Chvostek's sign is not necessarily indicative of tetany. At any rate, in an older child it means as a rule a neuropathic constitution, and is especially common in children showing vasomotor irritability, and in those suffering from orthostatic albuminuria.

The Effect of Certain Experiments Upon the Islands of Langerhans.

Although it is now generally believed that the islands of Langerhans are in some way related to the production of diabetes, this hypothesis has not yet been rigidly established by experimental demonstration. There are numerous observers who attribute to the islands other rôles in the physiology of the pancreas. According to the "balance theory"

of Laguesse there is a regular transformation of acini into islands and of islands into acini, depending upon the demands of carbohydrate metabolism. Still another conception regards the islands as exhausted alveoli, which are nevertheless capable of resuming their normal appearance and function. R. L. Cecil (*Journal of Experimental Medicine*, July 1, 1912) subjected these theories to further analysis by means of inanition experiments, by means of the exhaustion of the pancreas with secretin, and by means of the production of phloridzin and adrenalin diabetes. These experiments are repetitions of those already performed by others, with the improved feature that in the former the islands have actually been counted and measured and the averages obtained have been compared with those obtained from controls. According to Cecil's observations the pancreas of a dog subjected to inanition does not show any active transformation of acini into islands, nor do they demonstrate any notable increase in either the size or the number of the islands after overstimulation of the pancreas with secretin. Moreover, in phloridzin diabetes, as in adrenalin diabetes, the islands of Langerhans are not affected. As the result of these findings, Cecil comes to the general conclusion that the islands of Langerhans are not formed out of exhausted or degenerated acini, but develop from the ducts or acini with which they are often in direct continuity.

News of the Week.

Smallpox Closes up City.—Carbondale, Pa., has an epidemic of smallpox which has made necessary an order by the Board of Health closing all churches, schools, and theaters, and prohibiting all public gatherings. Up to August 22 twenty cases had developed, and several were under suspicion. The mayor has ordered compulsory vaccination and has the assistance of the Assistant State Commissioner of Health in handling the situation.

Spain Accused of Concealing Plague.—That there have been cases of bubonic plague in the Canary Islands for some years, and that this fact has been carefully concealed by the Spanish Government is the charge made by Dr. Mario Lebredo, Commissioner of Cuba, who was sent to Spain several months ago for the purpose of studying plague conditions there. Dr. Lebredo believes it possible that the infection in both Cuba and Porto Rico recently may have been carried from Teneriffe, Canary Islands, the attitude of the Government having made the examination and detention of Spanish ships entering Cuba seem unnecessary. The Spanish Government's instructions are said to be to fight the disease in every way known to science, but to deny its existence.

Reception to Visiting Scientists.—The German Medical Society of New York will hold a reception on the evening of September 18 in honor of the German and Austrian physicians who will come to this country to attend the International Congress of Hygiene at Washington. It is expected that several hundred physicians will attend the Congress under the auspices of the Deutsches Zentralkomite für aerztliche Studienreisen of Berlin.

Civil Service Examinations.—The New York State Civil Service Commission announces examinations to be held on September 22 for the following positions: Physicians, homeopathic or regular, at a salary of $1,200; and dentist, resident in State institutions, at a salary of $600 and maintenance. Further details and application blanks may be obtained from the commission at Albany, N. Y.

The United States Civil Service Commission will hold an examination on September 11 to secure eligibles from which to make certification to fill vacancies in the position of physician in the different services. Among the vacancies to be filled are nine in the Indian Service, paying from $1,000 to $1,200 a year. Candidates must be citizens of the United States and over twenty-one years of age. Persons desiring to take the examination should apply at once to the United States Civil Service Commission, Washington, D. C.

Pure Drug Bill.—The Sherley bill, which was passed by the House on August 19, amends the pure food act by providing that drugs shall be considered as misbranded if the package or label shall bear any statement, design, or device, regarding the curative or therapeutic effect of such article, which is false or fraudulent. This measure was prepared on the recommendation of President Taft following the decision of the Supreme Court in the Johnson case, in which it was held that while the pure food law as it then stood required all packages to bear labels accurately setting forth the constituents of drugs offered for sale, there was nothing that prohibited the making of false statements as to the curative power of such drugs.

Infant Deaths.—During the week ending August 17 there were in New York City 353 deaths of infants under one year of age, 55 less than during the corresponding week of last year. Among the 17,360 babies registered at the milk stations there was only one death during the week.

New Ophthalmic Hospital.—Plans have been prepared for the new building for the New York Ophthalmic and Aural Institute, which is to be erected at the southwest corner of Fifty-seventh street and Tenth avenue, New York. The building, which will be eight stories high, on a plot 45 by 75 feet, will be the largest hospital in the country devoted exclusively to the treatment of diseases of the eye and ear. The estimated cost is $200,000.

Health of the Canal Zone.—For the month of July, 1912, the total number of deaths from all causes among employees of the Isthmian Canal Commission was 28, making an annual average death rate per thousand of 6.84, the lowest so far recorded for the month. Sixteen deaths were due to disease, giving a general average for disease of 3.9, the rate among white employees being 5.92 and among the blacks 3.25. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Expansion at the University of Pennsylvania.—Plans are in process of completion for increasing opportunities for clinical work in the medical department of the University of Pennsylvania. These comprise the erection of a group of buildings at a cost of more than a million dollars, with equipment to cost not less than half a million. The present nurses' training school building is to be removed and the present hospital is to be replaced by an entirely new one. A seven-story surgical building will provide for an *x*-ray department, surgical wards, operating amphitheaters, laboratories, etherizing rooms, and recovery wards. A medical building of similar design and size will meet the

needs in the field of internal medicine. In the middle of these structures there will be an administration building separated from the others by buildings devoted to hospital purposes.

Public Service Training School.—The New York Bureau of Municipal Research desires to procure for its Training School for Public Service several physicians who wish to enter public health work, particularly one or two who would like to qualify as experts in making sanitary and health administration surveys of cities in different parts of the country. Stipends of from $900 to $3,000 will be paid according to previous experience and prospective immediate service of applicants. Field work will consist of analysis of board of health budget estimates, visits to milk stations, various forms of inspection, such as of slaughter houses, nuisances, milk shops, etc., statistical analysis, and tabulation, etc.

Dr. Joseph H. White of the United States Public Health Service has been asked to accept the position of chairman of the Board of Health of Boston, Mass., for which Mayor Fitzgerald has been for some time past seeking a desirable candidate. It is reported that Dr. White will accept the offer if his release from the Government service can be arranged.

Dr. Albert O. Zwick of Cincinnati, Ohio, has been nominated for Congress by the National Progressive party of Ohio, running against Congressman Longworth, ex-President Roosevelt's son-in-law. Dr. Zwick's slogan is to be, "Wipe out the Slums!" of which he has made use in his fight against tuberculosis.

Gifts to Charities.—By the will of the late Sarah Morris Ogden of Riverton, N. Y., the sum of $10,000 is bequeathed to the Philadelphia Home for Incurables and the sum of $1,000 to the Female Association of Philadelphia for the Relief of the Sick and Infirm Poor.

St. Luke's Hospital, New York, receives the sum of $10,000 by the will of the late Mrs. Catherine E. Daly, the bequest to be used to establish in memory of Henry E. Daly, the testator's husband, two beds for the benefit of "dramatic, minstrel, variety, and circus performers, one bed for a man and one for a woman."

By the will of the late Joseph Netter of Philadelphia the sum of $1,000 is bequeathed to the Jewish Hospital in that city.

The Ninth International Otological Congress was held in Boston August 12-16, under the presidency of Dr. Clarence J. Blake of Boston. The total registration was 410, of whom 25 were official delegates from foreign countries. The Tenth Congress will be held at Halle, Germany, in 1915. The officers elected were: *President,* Dr. Alfred Denker of Halle; *Vice-President,* Dr. Alexander B. Randall of Philadelphia; *Secretary and Treasurer,* Dr. Henry O. Reik of Baltimore.

The Southern Medical Association will hold its annual convention in Jacksonville, Fla., on October 12 to 14, 1912, under the presidency of Dr. J. M. Jackson of Miami, Fla.

Caledonia County (Vt.) Medical Society.—At the annual meeting held on August 14 the following officers were elected for the ensuing year: *President,* Dr. A. J. Mackay, Peacham; *Vice-President,* Dr. H. L. Pache, Danville; *Secretary-Treasurer,* Dr. H. H. Miltimor, St. Johnsbury.

New York and New England Association of Railway Surgeons.—The twenty-second annual session of the association will be held at the Hotel Astor, New York, on Wednesday, November 13, 1912. Dr. John B. Murphy of Chicago will deliver the address in surgery, and in addition a very interesting program has been arranged. Railway surgeons, attorneys, and officials, and all members of the medical profession are invited to attend. The corresponding secretary of the association is Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

Obituary Notes.—Dr. Dennis B. Nisbit of Eatonton, Ga., a graduate of the Medical College of Georgia, Augusta, in 1876, and a member of the Georgia State and Putnam County Medical Societies, died at his home on August 15, aged 57 years.

Dr. Edwin G. Steinmetz died at Hokendauqua, Pa., on August 13, at the age of sixty-eight years. He was graduated from Long Island Hospital Medical College in the class of 1867.

Dr. Manuel J. Manent of New Orleans, La., a graduate of the Medical Department of the Tulane University of Louisiana, in 1900, died at his home, on August 7, aged forty-one years.

Obituary.

JAMES EDWARD NEWCOMB, M.D.

New York.

Dr. Newcomb died at Lake Kushaqua, N. Y., on Tuesday, August 27, from cardiac and renal arteriosclerosis. He was born in New London, Conn., August 27, 1857, was graduated in arts from Yale College in 1880, and in medicine from the College of Physicans and Surgeons, New York, in 1883. After the usual term of service on the house staff of Roosevelt Hospital he entered into general practice in this city; but early began to specialize in laryngology, in which branch of medicine his studious habits, careful observation, and unusual abilities soon brought him distinction. He was for many years secretary of the American Laryngological Association and was its president at the meeting in Atlantic City in May of this year. He was professor of laryngology at the Cornell Medical School, and consulting laryngologist to the Roosevelt Hospital. He was also a member of the Medical Societies of the county and State of New York, of the New York Academy of Medicine, of the American Academy of Medicine, of the West End Medical Society, of the Society of the Alumni of Roosevelt Hospital, and of the Hospital Graduates' Club.

Dr. Newcomb was in earlier years a frequent contributor to periodical literature, and wrote numerous articles on the nose and throat in the "Reference Handbook of the Medical Sciences" and in the "Twentieth Century Practice of Medicine." He was editor of the American edition of Grünwald's "Atlas of Diseases of the Mouth, Pharynx, and Larynx," and was the author, in collaboration with Burnett and Ingals, of a treatise on "Diseases of the Nose and Throat." For over twenty years he was a valued member of the editorial staff of the Medical Record, contributing many editorial articles and reviews on laryngological subjects.

A man of culture and sound learning, an entertaining speaker, broadly charitable, tolerant of the views of others though firm in his own beliefs, a true and steadfast friend, Newcomb will long be held in affectionate remembrance by all whose privilege it was to know him.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OUR TWO SCHOOLS OF TROPICAL MEDICINE—ROYAL SANITARY CONFERENCE AT YORK—TUBERCULOSIS, TUBERCULIN DISPENSARY SYSTEM, BATHING, LUNACY, PHARMACEUTICAL CONFERENCE—ITEMS —OBITUARY.

London, August 9, 1912.

Last week Mr. A. Chamberlain made a powerful appeal at the London Chamber of Commerce on behalf of the London School of Tropical Medicine—not merely on the ground of humanity, in saving life and lessening suffering, but, he told the city merchants, because we are becoming more and more dependent on tropical and semi-tropical countries and everything tending to make them more healthy, tended to promote trade, lessen its expense, increase the possibilities of development and so worked for the prosperity, not only of the district concerned but of the empire of which it formed part. He specially appealed to public companies and their shareholders, mentioned that some had already responded and about £19,000 had been given in response to letters he had himself writen in the last three or four weeks. There was good hope that still further saving of life would be secured in the future—much as had so far been attained.

The Liverpool Tropical School is also in need of funds for extension. Its workers hope to get a building with fuller facilities for teaching as well as a larger museum for entomology, helminthology, and protozoology. A special tropical ward in connection with the school, it is hoped, will be built at the Royal Infirmary close by, which would much exceed the present arrangements in convenience. It is also proposed to establish a branch laboratory in West Africa. Exhibits illustrating the mode of transmission of tropical diseases were sent at great cost to the Franco-British, Japanese, British, and Dresden Exhibitions, and this mode of educating all interested is intended to be continued if funds are forthcoming. The greatest work of this school has, however, been sending out expeditions to study tropical diseases in their home. In this way skilled men study the diseases in their usual environments and bring back material to work up for further investigations under laboratory conditions. The school has sent out about thirty such expeditions, and I need not tell you how fruitful has been the harvest, especially in the discoveries regarding yellow fever and sleeping sickness.

The eugenists followed up their International Congress, with an appeal for funds to put them on a pecuniary basis so as "to ensure the progress of the nation, if not to guard against an actual retrograde movement." They afterwards put in an appearance at the annual conference of the Royal Sanitary Institution in York, where the differences between the "better dead" and the "better not born" schools were in dispute. The former held that infant mortality, tuberculosis, alcoholism, and other fatalities should be regarded as excellent means of weeding out the worthless—extremists saying that the lethal chamber would be the best way of getting rid of the unfit. The other school conceded the right to live in all cases, but not the right to become parents. The talk of lethal chambers they stigmatized as "rubbish," and some people outside declare its advocates should begin at home and set an example of self-sacrifice before proposing it for others. The notion that medical men would serve on a committee to decide who should be put away was at once repudiated, and the audience reminded that the doctor's mission was to save life. It might be added, also, to remove the causes of imperfection when known and possible and where unknown to discover them.

A lady speaker on classes for mothers said textbook preparation did not suffice and related the following talk of two women: "What do you think of the board schools teaching the girls to manage babies?" Reply: "How are they to teach a girl to manage a thing as wriggles by holding a thing as don't wriggle?"

In the light of the foregoing it is as well to call to mind that the archbishop in his address had confessed a willingness to annul marriages when within a certain time insanity, epilepsy, etc., developed. But he admitted eugenists went too fast and in reading some of their views he had a sort of nightmare of a race physically fit, but mentally, morally, and spiritually sterile.

Tuberculosis claimed more attention from the congress. The tuberculin treatment was brought forward by Drs. Fraser and Clark, who have charge of the dispensary established by the municipality of Porstmouth. They gave a clear and sufficient statement of the treatment and the cases (433 in number) admitted in the last year. They are convinced of the value of the treatment and consider that its extension under municipalities, as in this case, is the most desirable plan. They would have waited for further experience before addressing the profession, but have received so many inquiries from others proposing to follow that they thought best to make a statement now. The dispensary they regard as the center of the scheme which should embrace hospital, sanatorium, open-air schools, house supervision, etc. In fact, the scheme should include all methods of dealing with cases in all stages, the dispensary admitting, diagnosing, and treating all that seem likely to benefit by the tuberculin method and passing others on to the institution which seems more suitable.

A discussion on tuberculosis in animals in relation to the public health was also held. Professor Dewars, presiding, emphasized the duty of government to do something to meet the risk from consuming the meat and milk of tuberculous animals. For twenty years and more the health of live stock had been committed to a government department which simply looked on without moving a finger to prevent while the disease was carrying off tens of thousands. It was time our honest endeavor was made to prevent the spread of the scourge.

The question of compensation was discussed. The cooperation of the farmer could be secured if he were met with some help, but one could not be expected to sacrifice an animal when his neighbors did not. Sir Shirley Murphy said the way to induce farmers to take all precautions was to bring it home to him that tuberculous milk or meat could not fetch the price of healthy articles. He did not favor insurance unless on a mutual basis, when the farmer would have a fixed interest in prevention. Dr. Surg.-Gen. Pryer said the Admiralty required in their milk contracts that the cows be tested by tuberculin annually and that inspection by a veterinary surgeon be made every six months.

Mr. Collins moved a resolution calling on the

government to appoint a conference of cattle owners, public authorities, and insurance companies to consider the eradication of the tuberculous milch cow. The chairman thought such a conference would not come to an agreement "until the crack of doom," but the resolution was adopted.

Dr. R. H. Quine caused no little amusement by a paper on the washing habits of the English in which he maintained that the nation is not so clean as supposed. This has set the wags of the general press to work with articles on "the tub" and other appliances for personal hygiene, and the loss of one more national characteristic—a press discussion, in fact, well adapted for the "silly season."

Dr. Mott contributed a paper to the effect that the increase of lunacy of which so much has been heard was more apparent than real. Since then Dr. Forbes Winslow has published a protest against that view and says rather that "we are rapidly approaching a mad world," for as civilization advances so lunacy increases. Fifty years ago we had one lunatic in 575 of the population, now one in 236. At this rate, Dr. Winslow says, that in 300 years there will be more insane than sane people in the world.

This year's meeting of the British Pharmaceutical Conference has been held in Edinburgh, president, Sir Edward Evans, who, in his address mentioned the extent to which drugs are cultivated in the United States. He instanced a number and advocated the same being extended here, perhaps under a department of the Board of Agriculture at Mitchaw, near London, and grow lavender, peppermint, and a few others, but only as a private enterprise. The next year's meeting will be the jubilee and is to be held in London. The remarkable increase of the trade in cascara was referred to—at one time a very small industry; now it was said amounting to 1,000 tons a year. To yield this amount some 100,000 trees were said to be destroyed in the forests of northern California, Oregon, and part of British Columbia. One might very well predict a shortage, but that might not be a calamity for the major part of it is certainly not consumed on the prescriptions of the profession.

On Tuesday a statement was circulated on the authority of the Local Government Board that a boy of seven was admitted to the Liverpool Royal Infirmary and operated on for appendicitis on July 27. A gland removed from the groin was found to contain plague bacilli. The diagnosis was confirmed in the laboratory of the Local Government Board. All precautions are being taken to prevent the spread of the disease, and so far no other case has occurred. The source of infection has not been traced.

The daily press is assuming airs on the ground that Dr. G. E. Morrison, who has been selected by the Chinese Government as its political adviser, is a British journalist. Both words are correct. British as an Australian born—journalist as having after an eventful career, settled down as special correspondent in China. But we might as well vaunt ourselves that he is a doctor, took his degree at Edinburgh and for some time practised in Paris. It was, however, as an explorer that he made his chief reputation. It was he who walked across the Australian continent from the north coast to Victoria and followed that exploit by walking across China and Burma. The West Indies, Spain, Morocco, and other places know him. At the siege of the Pekin legations he was present and when it was reported that they had fallen the *Times* published the obituary of their able correspondent, so perhaps he enjoyed the sensation of reading his story, for the legations had not fallen and the doctor is still very much alive.

Dr. A. N. Stevens, M.O.H. for Yarmouth, issued notices warning the people not to eat mussels from the river, but says in his report one woman who ate a quantity and had typhoid admitted that she had read the notice on the wall of her own house.

Mr. Arthur Trehorn Norton, C.B., formerly surgeon to St. Mary's Hospital, died on August 4, aged 71. He fulfilled his curriculum at St. Mary's school and became member of the Royal College of Surgeons in 1862, proceeding to the fellowship in 1867. He was then elected on the surgical staff of his hospital, to which eventually he attained the full surgeonry and the lectureship on surgery in the school. He was also for a time examiner on the subject in Durham University and served in the Volunteer Medical Staff Corps, obtaining the Decoration and the rank of Lieutenant-Colonel. He rendered service in France in the Franco-Prussian War, for which he was awarded the Gold Medal. He was Associate of the Order of St. John of Jerusalem and was created C.B. in 1897. His "Osteology for Students" reached a second edition, as did his "Affections of the Throat and Larynx." He translated Bernard and Huette's "Operative and Surgical Anatomy."

OUR PARIS LETTER.

(From our Regular Correspondent.)

SOCIETY OF SURGERY—TREATMENT OF HEMORRHAGES BY MEANS OF DIRECT TRANSFUSION OF BLOOD—GENERAL ANESTHESIA INTRODUCED BY MEANS OF INTRAMUSCULAR INJECTIONS OF ETHER—MEDICAL SOCIETY OF THE HOSPITALS—INFLAMMATORY TUBERCULOSIS OF THE URINARY APPARATUS—NECROLOGY, MARC SÉE.

Paris, August 15, 1912.

The treatment of hemorrhage by direct transfusion of blood was the title of a paper read before the Society of Surgery by Pierre Delbet, who reported two observations as to the efficacy of this treatment, one by Guillot and the other by Helly of Havre. The first case was that of a woman 40 years of age who had severe hemorrhages resulting from a uterine fibroid. She was transfused with blood from a vigorous and healthy man aged 35 years. Following this procedure the hemorrhages ceased. The second case was that of a woman 32 years of age who suffered from cancer of the stomach, which occasioned severe hematemesis and melena. Transfusion was performed by means of the anastomosis of the radial artery of a healthy man with the saphenous vein of the patient, as the result of which the hemorrhages ceased. Delbet after having studied the literature of this subject has arrived at the following conclusions: Transfusion of blood is only rarely necessary in the treatment of hemorrhages whose source can be found and controlled; but it is indicated above all in the case of anemia secondary to repeated hemorrhages, whether these are due to hemophilia or to visceral lesions. It is of value not only as a means of replacing the blood lost but also as a powerful hemostatic.

Tuffier recommends as a preliminary to the performance of transfusion the determination of the Wassermann reaction in the donor. The operation

itself requires rigorous asepsis. The two subjects should be placed on two beds in such manner that the head of one individual is opposite the feet of the other. The radial artery should be exposed for a distance as long as possible, while the segment of vein exposed need not be quite as long. For the union of the vessels one should employ Elsberg's cannula. The time during which the blood should be allowed to flow is variable; in general this time should be from 20 to 30 minutes. The indications of transfusion are mechanical hemorrhages, hemorrhages due to dyscrasia, and as a means of combating infections and neoplasms.

General anesthesia by means of intramuscular injections of ether was the subject of a paper presented before the Society of Surgery by Broca. This method has been proposed by Descar-Pentries of Roubaix. The latter employs a syringe holding from 20 to 30 cubic centimeters and a needle about 7 centimeters long. With the sterile syringe and needle the injection of ether is made quite slowly. The patient begins to experience severe pain; then he gradually falls into a light sleep; in fifteen to twenty minutes anesthesia is established, and continues for fully one-half hour. For the production of surgical narcosis it is necessary to inject as many grams of ether as the patient weighs in kilograms. The inventor of this method has never observed any accidents resulting from it. Jean-Louis Faure has reported the case of a woman aged thirty-five years suffering from a cancer of the tonsils and velum palati. Operation was performed under intramuscular ether anesthesia with the greatest satisfaction. Peugniez of Amiens has employed this method without any good results although he used 60 cubic centimeters of ether. Walther has tried this method but does not believe that it should be further practised. The anesthesia requires a long time to be established, the subsequent vomiting is not avoided, and the initial pain accompanying the injection is extremely severe. Quenu stated that this method should be abandoned. The anesthesia is obtained after a long time, and it is frequently necessary to resort to chloroform to quiet the pain resulting from the injection.

Inflammatory tuberculosis of the urinary tract was the subject of a discourse before the Medical Society of the Hospitals by Poncet. This observer believes that urinary tuberculosis is a frequent manifestation of this disease. To inflammatory tuberculosis he would attribute certain forms of nephritis and certain cases of orthostatic albuminuria. He believes that leucoplasia of the bladder and ureteral polyps are fundamentally of inflammatory tuberculous origin. Siredey stated that ureteral polyps are more frequently caused by gonorrhea than by tuberculosis. Dufour stated that there is frequently a close relationship between tuberculosis and renal lithiasis. Achard has also observed this association in a case of tuberculous pyelonephrosis; the calculi had a center of uric acid surrounded by concretions of phosphate of soda. Barth ventured the opinion that Poncet was too speculative in his ideas on this subject. It was difficult to admit that a large number of diseases, such as diabetes, are of tuberculous origin.

Marc Sée, member of the Academy of Medicine and of the Surgical Society, has just died. In spite of his old age his death was sudden. By his teaching and writings, Sée maintained an honorable place in the group of men who toward the middle of the last century sped the art of medicine along the fertile path of scientific observation. Before the time of Farabeuf he was chief of the anatomical division of the medical faculty of Paris; at that time he published the results of his studies on the valves of the heart. In this work he explained the function of the mitral and tricuspid valves and the rôle of the columnæ carneæ in such a clear manner that at the outset his ideas were adopted by all, and remain to this day a classic. This labor alone will serve to perpetuate the memory of Marc Sée. Besides he had the honor of collaborating for a long time in the publication of the fourth and fifth edition of the Descriptive Anatomy of Cruveilhier, which was a classic for many generations of students.

OUR BERLIN LETTER.

(From our Regular Correspondent.)

THE GERMAN SURGICAL SOCIETY—EPIDURAL INJECTIONS IN SCOLIOTIC SCIATICA—FREUND'S OPERATION IN APEX TUBERCULOSIS—SURGERY OF GASTRIC ULCER—X-RAY MEDICATION IN GASTRIC SURGERY—COVERED GASTRIC ULCERS—ECK'S FISTULA IN CIRRHOSIS OF THE LIVER—DIAGNOSIS AND TREATMENT OF CHRONIC PANCREATITIS—CONGRESS OF INTERNAL MEDICINE—GASTRIC RÖNTGENOGRAPHY—THERAPEUTIC EXPERIENCES WITH RADIUM AND THORIUM—THORIUM IN LEUCEMIA—TOXIC ORIGIN OF PERNICIOUS ANEMIA AND ITS ANTITOXIC TREATMENT—SURGICAL TREATMENT OF CHRONIC PULMONARY TUBERCULOSIS—SALVARSAN TREATMENT OF SCARLATINA—RENAL FATIGUE.

Berlin, July 15, 1912.

Of the large German medical societies whose meetings were nearly all held during the month of April the following brief report may be of general interest. At the Forty-first Congress of the German Surgical Society, Heile of Wiesbaden read a paper on the treatment of scoliotic sciatica by means of epidural injections. In these cases the sciatica is the result of irritation of the posterior roots by the scoliotic condition of the spine. Through the intervertebral foramina of the spine there were injected with greatest success 100 c.c. of physiological salt solution. W. Kausch of Berlin reported his results in Freund's operation in apex tuberculosis. Of the nine cases that have so far been operated upon, five have been operated upon by the speaker. The operation is not dangerous. Only cases should be operated upon in which the disease does not extend below the second rib. In two cases in which this caution was not observed the result was unsatisfactory; in the other cases marked improvement and cure followed and has been permanent three and four years after the operation.

The surgical treatment of gastric ulcer occupied a great share of attention. Riedel of Jena reported 18 cases in which an ulcer of the lesser curvature was resected and in which the patient remained healthy for years afterward. Of greatest importance in securing a good result is the avoidance of injuring the edges of the wound by means of the pressure of the clamps. Kocher of Bern reported 80 cases operated upon, in 70 of which gastroenterostomy was employed and in only 10 of which resection was resorted to. Of 64 of the former cases, 50 have remained healthy during the following ten years. Since in the case of patients on whom gastroenterostomy has been performed carcinoma is found less frequently than in the case of

untreated ulcers, it must be accepted that gastro-enterostomy prevents cancer probably through the elimination of the stimulus of hyperacidity. The discussion was taken up by twenty-two members.

The value of radiography as a means of defining the indications in surgery of the stomach was the title of a paper based upon 800 examinations by Haudek of Vienna. Strict indications for operation are the demonstration of sacculation, hour-glass formation, and gastrectasia. It is now possible to determine by means of the *x*-rays the seat of an ulcer. Schnitzle of Vienna discussed the subject of covered gastric ulcers, that is ulcers to whose outer surface other organs are united by adhesions, so that when the ulcers perforate peritonitis is prevented. In the past two years he has operated upon two cases in which the liver was adherent to the site of the ulcer before perforation. Paul Rosenstein of Berlin reported a case of cirrhosis of the liver in a woman sixty years old in whom he established an Eck's fistula. Five months have elapsed since the operation, during which period ascites has been of slighter degree and of less frequent recurrence. This is the first instance of an operation of this kind being performed in a human being.

The diagnosis and therapy of chronic pancreatitis was the subject of a paper read by Gulecke of Strassburg. Of eight cases he made a correct diagnosis in five. Most characteristic is the pain radiating from the left shoulder and independent of the taking of food. Furthermore, of diagnostic importance are the doubled-up attitude of the body and the deep sensitiveness in the epigastrium. A resistance in the region of the pancreas is found in one-half of the cases. The urine voided after an attack contains sugar. By the operation of short-circuiting the pylorus the patients were improved but not cured.

The service of the *x*-rays in the recognition and treatment of diseases of the stomach was the subject discussed in a most thorough manner at the Congress of Internal Medicine, April 29, 1912, by Rieder of Munich. The subject of radium and thorium also came in for extended discussion. Falta, Kriser, and Zehner of Vienna reported the results of their therapeutic experience with thorium-X, particularly in leucemia. Thorium-X causes a rapid diminution in the volume of blood in animals, in normal individuals, and in cases of leucemia. In animals treated with thorium the splenic pulp, the adenoid tissue, and the chromaffin cells degenerate. In six cases of leucemia with a leucocyte count of 150,000 to 1,000,000, five were made normal by this method of treatment, and in one case the number of leucocytes was greatly diminished. At the same time the spleen and hypertrophied lymph nodes diminished in size, and many of the latter disappeared entirely. P. Lazarus believes that the radioactive substances have no specific action. All other chemically active rays have the same effect. The speaker could not confirm the rapid decomposition of uric acid under the influence of radium. He believed that the best effect was obtained by the injection and not by the inhalation of radium.

The origin of pernicious anemia was investigated by Lüdke of Würzburg, and Fejes of Buda-Pest. They were able to isolate from the intestinal flora hemolyzing substances that evoked pernicious anemia in monkeys. By means of these poisons the speakers were able to produce an antiserum that was capable not only of preventing but also of curing the disease. Fränkel of Badenweiler discussed the surgical treatment of chronic pulmonary tuberculosis. In selected cases the operation consisted first in the resection of portions of the ribs posteriorly adjacent to the spine, from the first to the eighth ribs; and then after an interval of time, the resection of similar strips two to three centimeters long from the anterior portions of the ribs next to the sternum. In twelve cases the practically painless operation was well borne, and good results were obtained.

The treatment of scarlatina with salvarsan was reported by F. Klemperer and Woita of Berlin. Of 49 cases of severe scarlet fever not treated with salvarsan the mortality was 24.5 per cent. Thirty-nine very severe and 21 mild cases were treated with salvarsan. Of the severe cases there died only 8.3 per cent. The fatigue of renal function was the subject of a paper by Schlayer of Tübingen. In various forms of inflammation of the kidneys pronounced symptoms of this fatigue develop under the influence of certain disturbing agents. These include the diuretics and sodium chloride. The fatigue is observed most frequently in the case of chronic parenchymatous nephritis as well as in interstitial nephritis with a normal or diminished quantity of urine. The investigations show that in these cases the renal vessels are damaged. If fatigue develops from the use of diuretics or common salt, every other disturbing factor is all the more harmful.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

VALUE AND TECHNIQUE OF THE TEST BREAKFAST—ABDOMINAL ADHESIONS CAUSED BY PRESENCE OF SILVER WIRE SUTURES—APPARATUS FOR SHORTENING OF LEG.

VIENNA, August 15, 1912.

THE value and technique of the test-breakfast was the subject of a lecture recently delivered by Professor Schlesinger. The majority of patients even at the first attempt can introduce the stomach tube themselves. In hyperacidity with an acidity exceeding 60 the typical ratio of the free hydrochloric acid to the total acidity is 3 to 4, or even closer. In the case of normal acidity, with a total acidity of 40 to 60, the ratio is 2 to 3. In subacidity with a total acidity less than 40 the ratio is 1 to 2 or even wider. Subacidity with a close ratio signifies dilution (the dilution-secretion of Strauss or swallowed saliva); hyperacidity with a particularly wide ratio is suggestive of the presence of mucus (acid catarrh). Upon repeated siphonge the following pronounced change is observed: A rise in the figures for free hydrochloric acid and total acidity; a coincident narrowing in the ratio between them; and a diminution in the amount. This result suggests a transient disturbance of motility (atony) as a frequent complication of gastric diseases. Puzzling cases of hyperacidity can be discovered (larval hyperacidity), as well as cases of ulcer with an initial subacidity. Low acidity figures found in cases of alimentary hypersecretion are caused by an accompanying atony, for with repeated siphonage the genuine type of hypersecretion comes to the foreground. This transformation resulting from repetition of the test-breakfast does not occur in well compensated pyloric stenosis. But it does occur in the frequent combination of narrow pylorus (duodenal type of stenosis) with muscular insuf-

ficiency. In these cases are found an elevation and closer approximation of the figures. Later these figures remain constant with a coincident increase in the gastric contents (over 150 cubic centimeters). In acid catarrh the characteristic change is a lowering in the free acidity with a constant or even a diminishing total acidity.

Adhesions between the abdominal wall and intestine were discovered in a case reported by von Frisch. For a long time the patient, a woman, had suffered from intestinal disturbances until finally symptoms of ileus presented themselves. At laparotomy there were discovered adhesions extending from the posterior aspect of the linea alba to the small intestine, and beneath these adhesions a loop of gut was strangulated. After freeing these adhesions von Frisch discovered on the posterior aspect of the linea alba the projecting ends of a few pieces of silver wire that had remained after an operation for the closure of an umbilical hernia several years previously. The suture had cut through to the peritoneum and by irritation of the intestine had resulted in the formation of adhesions. This form of suture is apt to break if continually bent as the result of the physiological mobility of the organ or tissue into which the suture has been introduced, as in the case of a pateller fracture. If the tissue is not moved the suture rarely breaks.

An apparatus for pronounced shortening of the leg has been devised by Oscar Semeleder. The opportunity presented itself in the case of an eighteen-year-old girl who in infancy had suffered from tuberculous osteomyelitis of the femur. As a result both epiphyses of the femur had been destroyed, and the growth of the bone ceased. The amount of shortening of the affected leg was 24 centimeters. Semeleder constructed an apparatus with an artificial foot provided at the lower end. By means of suitable leverage the patient was able to utilize her atrophic muscles in locomotion, which she had not been able to do with the former apparatus. This exercise enabled the wasted foot to develop. In spite of a flail joint and genu varum the apparatus was carried up to the knee, and by means of a lateral position of the stepping surface of the apparatus the previous disadvantages with reference to the deformity of the knee were corrected. The patient, who had previously been unable to walk without pain, was able now to walk for hours without any difficulty.

Progress of Medical Science.

Boston Medical and Surgical Journal.

2. Our Present Knowledge of the Physiology and Chemistry of Gastric Digestion as Applied to Vomiting in Infancy. A. C. Eastman.
3. Pneumonia Not a Rare Complication of Heat Prostration. W. D. Reid.

2. Vomiting in Infancy.—A. C. Eastman states that Cannon has demonstrated that a certain normal tonus of the muscles of the alimentary tract is necessary for the normal peristaltic action. This tonus is stimulated by a vagus reflex due to mastication and the sense of taste, and when once stimulated is continued by the rhythmical peristaltic action due to the pressure of food. Any diminution of muscle tonus will delay peristaltic action in the stomach and tend toward lessened motility. Chapin has emphasized the point that atrophic infants as a rule are fed too often and as a result fermenting food is left in the stomach to contaminate succeeding feedings, and gradually a dilated stomach results with further loss of muscle tone. Vomiting in breast-fed infants is probably due almost always to a high fat percentage, usually caused by a lack of exercise and overfeeding on the part of the mother. The remedy naturally lies in regulating the mother's daily life, and, if necessary, diluting the milk. In bottle-fed babies the causes are more numerous. In the first place a large number of persistent vomiting cases are the result of too strong a formula at the time of weaning. There are certain cases of marasmus and atrophy in which the lack of muscle tonus is often fostered by the continued use of too dilute a formula. Too high a percentage of fat may also be a definite cause of persistent vomiting.

3. Pneumonia as a Complication of Heat Prostration.—W. D. Reid notes that among 160 cases of heat prostration pneumonia occurred in 10.7 per cent. and was the cause of 20 per cent. of the 44 deaths. Though not more frequent after heat stroke than after heat prostration, in the former pneumonia was much more fatal. Of lobar pneumonia there were seven cases with two deaths. Of bronchopneumonia there were ten cases with seven deaths. The greatest number of cases occurred between 20 and 30 years, but the severest mortality was in the sixth decade of life. Alcohol and arteriosclerosis were fatal complications. Erysipelas and empyema necessitatis were sequelæ in two of the cases. It is pointed out by the author that medical textbooks minimize or fail to mention the importance of pneumonia as a complication of heat cases. However, it occurs in 10 per cent. of these cases and it causes 20 per cent. of the deaths. The pneumonia does not differ from that due to other causes. The greatly depressed condition of the heat cases and the sometimes over-vigorous measures employed to reduce the body temperature seem sufficient and probable causes.

6. The Pathology of Chorea. F. A. Hulst.
7. Chorea. F. C. Eastman.
8. The Proteins. D. D. Van Slyke.

1. The Prevention of Insanity.—A. J. Givens alludes to the tendency to expend time, labor, and money more in dealing with the results of mental diseases than in preventing these diseases; and to the wastefulness and danger of pursuing such a policy. There is an apparent connection between increasing longevity and increasing insanity. The marriage of the unfit should be prevented. There is urgent need for the adoption of more practical measures for the lessening of the production, sale, and consumption of alcoholic beverages. There is a disproportion of foreign to native born insane, and a necessity for the distribution of the foreign element outside of cities. There are unappreciated opportunities offered by New York State and New England for the health-preserving life of the country.

3. Contagious Diseases of Childhood.—C. Herrman emphasizes the following points: As practical sanitarians physicians should know how contagious diseases are usually spread, not how they may be occasionally spread. These diseases are spread by persons and not by things. In the vast majority of cases the infection is due to contact either with a recognized or an unrecognized case or a carrier. The spread of contagious disease through the air, through desquamating scales, and through healthy third persons, not carriers, seldom occurs, and for prac-

tical purposes may be neglected. The disinfection of fomites, rooms, etc., is to a great extent unnecessary, especially since all infected individuals and carriers cannot be controlled. The carrier represents the crux of the problem. This difficulty will probably never be entirely overcome. On account of the existence of carriers, isolation, disinfection, improved medical school inspection, and special hospitals alone cannot have a marked influence on the reduction of morbidity. This reduction can be accomplished only by a method of temporary or permanent immunization against these diseases.

4. The Glycyltryptophan Test.—G. A. Friedmann reports the results that he has obtained with this test in nineteen cases in addition to the twenty-one previously reported. Only once in the first series of cases was this test positive in benign pyloric obstruction. This occurred with an enormous amount of sarcinæ in the contents of the stomach on fasting. On the other hand, the test was found frequently positive in gastric cancer. In this disease the test is of value, but cannot be considered pathognomonic.

5. Prognosis of Tuberculosis of Larynx.—S. von Ruck calls attention to the following points: Tuberculous changes are present in the larynx of patients suffering from pulmonary tuberculosis much more frequently than is generally recognized. The disease in the larynx in its early stages causes, as a rule, no definite or but slight subjective symptoms. For this reason the physical examination of every tuberculous patient should include, as a matter of routine, as much the inspection of the larynx as an examination of the chest. Slighter degrees of thickening of the mucosa which many observers are willing to accept as catarrhal are not infrequently tuberculous in nature, and may well suggest to the laryngologist who notes them in the course of his routine practice the propriety of a physical examination of the chest. The prognosis of tuberculosis of the larynx in the earlier stages is no worse, von Ruck maintains, than is that of the disease in the lungs.

6. The Proteins.—D. D. Van Slyke states that these are amphoteric electrolytes capable under proper conditions of combining with either alkali or acid. They are optically active. Many of the most striking physical properties of the proteins as a class bear no relation to their chemical composition, but are due to the fact that these substances are colloids. Similar to other colloids the proteins form solutions of almost no osmotic pressure, and have an unusual capacity to adsorb other substances in solution and to be adsorbed themselves. Adsorption is the term used to designate the concentration of a dissolved substance in the surface layer of the solvent. In discussing the chemistry of protein assimilation the author states that the explanation that the proteolytic products are resynthetized into protein while passing the intestinal wall must now be given up for the simpler one that the products enter the blood directly and are taken directly from it by the body cells. By the delicate and quantitative nitrous acid reaction the author has succeeded in demonstrating that amino acids are constantly circulating in the blood, although they are taken from it so rapidly by the tissues that they do not accumulate in amounts sufficient for isolation by present methods. It does not appear that the liver removes or destroys the amino acids before they reach the other tissues. During the height of digestion the blood from the femoral artery shows almost as much amino acid nitrogen (within one milligramme) as blood directly from the mesenteric vein. The amino acids entering the blood from the intestine circulate through the entire body, and apparently are offered directly to all of its cells for their individual necessities, to be either burned as sources of energy, or synthetized to form new cell protein.

2. Treatment of Cancer with Body Fluids.—E. J. Ill and W. D. Minningham report the results they have obtained in the treatment of twenty-seven cases of carcinoma and sarcoma by means of injections of ascitic fluid from a cancerous patient. The fluid used was the same kind as that employed by Hodenpyl. The fluid was drawn under the most careful aseptic conditions into sterilized bottles which were kept in a refrigerator, and all injections were given by siphoning the fluid directly from the container through a sterile rubber tube to the lower end of which a needle was attached. No cures were obtained, but the improvement in subjective symptoms was very marked in most cases and the last reports of some patients were that this improvement still continued. In one case where there was glycosuria this discontinued during the time of injection, but reappeared on discontinuance. Only one of the patients knew the character of his disease while being treated.

4. Bacterial Etiology of Acne Vulgaris.—M. Haase reviews at length the principal literature of the subject and notes that a diversity of opinion exists at the present time as to the bacterial etiology of acne. That there is a bacillus constantly present in all enlarged sebaceous follicles after the age of puberty, which may remain harmless under normal conditions, is probably the present view of dermatologists. The preponderance of opinion is in favor of its pathogenicity in susceptible individuals. Acne, in all of its various clinical manifestations, is apparently due to this bacillus which may appear under different forms in different conditions. The author has employed a stock vaccine of this bacillus in a number of cases, and, while he cannot claim for it the brilliant results obtained by some observers, he has found it so beneficial that he would be loath to treat a patient without its assistance.

7. Recent Advances in the Knowledge of Typhus.—J. Goldberger and J. F. Anderson conclude that satisfactory evidence has not yet been adduced that the blood of the monkey infected with typhus is virulent in the prefebrile stage. They also conclude that the blood of the monkey may still be virulent twenty-four to thirty-two hours after the return of the temperature to normal. Just as a considerable number of leucocytes are entangled and carried down by the red blood cells in centrifugating blood, so, they believe, is the virus carried down by the precipitated blood cells. Transmission by the louse apparently explains why typhus has been a disease peculiarly associated with misery and poverty, why it has been a

vagabond's disease, and a disease of jails and army camps. It has been demonstrated that this disease instead of being the exotic plague that it has almost universally been considered, has actually been endemic in this country for many years.

8. Immunity and Specific Therapy in Experimental Cancer.—I. Levin states that Wassermann's results obtained by means of chemotherapy seem to be the most successful of all those reported. The presence of immunity in the tumor animals makes it quite certain that ultimately a specific method of treatment in experimental cancer will be found. But it is impossible to predict whether the methods of chemotherapy, serotherapy, or ferment therapy will be the most fruitful of results. Chemotherapy is not the ideal method of treatment, but seems the most promising at present. It is difficult to predict the chemical nature of the most successful drug of the future, though one does not need to search for a substance absolutely fatal to the life of the tumor cells. The end may be achieved when a substance is found that will possess the power of arresting the active proliferation of the tumor cells.

10. Preservation of Tissues and Its Application in Surgery.—By A. Carrel. (See MEDICAL RECORD, June 29, 1912, page 1245.)

11. Prophylactic Vaccination Against Epidemic Meningitis.—A. Sophian and J. Black state that it is probable that the immunity produced by meningitis vaccination lasts for a long time, at least for a year. Vaccination is followed by an immediate febrile reaction, febrile leucocytosis, and an increase in immune body content, as determined by agglutination and complement fixation tests. Complement fixation tests will probably give the most satisfactory results, the agglutination and opsonin tests with the meningococcus, as with other Gram-negative cocci, giving frequently very irregular results. All evidence, especially the experimental, points to the efficacy of the injection of dead meningococci for prophylactic vaccination, as a measure which would confer considerable immunity in most cases, probably partial in all, against the infection of epidemic meningitis. It is very likely that only a moderate degree of immunity will give very considerable or complete protection against epidemic meningitis, which is caused by an organism of low virulence, infecting only a very small percentage of those who are exposed and who harbor the organism temporarily in their noses and throats. It is likely that if the disease subsequently develops in those vaccinated, it will be considerably modified and will run a much milder course with much better outlook for recovery, as is seen in those who develop smallpox after vaccination.

12. Erythromelalgia.—G. A. Moleen states that this disease is seen in association with diseases of the spinal cord and peripheral nerves, but is occasionally seen in a pure form. It is often difficult to differentiate it from the neurotic edemas which it somewhat resembles. The pain in some cases would appear to be the result of disturbance in the peripheral nerves, the posterior roots or, possibly, the lateral columns of the cord, while in other cases the burning and aching might be due to mechanical irritation of the peripheral nerve-endings primarily. In the treatment, rest in bed has been in most severe cases already made necessary by the pain aggravated by the upright position. In view of the vasomotor theory in the production of vasoconstrictor paralysis, the apparent influence of suprarenal substance in the author's case would seem to justify its use in plain or uncomplicated cases. Constitutional treatment is usually indicated to overcome the results of inactivity and confinement. A rubber bandage may at times render it possible for the patient to be on his feet with less discomfort and thus contribute to the betterment of his general condition.

8. Industrial Employment of Married Women: Its Influence on the Birth Rate and the Sex Ratio at Birth. H. R. Jones.
9. Observations on the Neuron. H. Campbell.

1. The Decline in the Birth Rate and Death Rate.—Sir Shirley P. Murphy believes that much of the well-known decline of the death rate, not only in England, but also in Europe generally, which has occurred during the past fifty years, is a natural phenomenon which has appeared independently of the designs of man. The author does not deny that much of the improvement of the conditions of life, tending, as it does, to increase resistance to disease, is due to human agency, but he desires to show that, making full allowance for what man has done, nature has largely determined the decline of the death rate. Passing to a consideration of the birth rate and its parallelism to the death rate, both in London and elsewhere, the author compares definitely the behavior of the rates in three groups of districts, the grouping being based on the social condition of the parents. The surprising conclusion is reached that the decline in both birth rate and death rate has been least in the most favored classes. The author suggests that the rates of birth and death are so intimately connected that they are probably interdependent; and further, that inasmuch as fertility is inherited in man, and susceptibility to some diseases is possibly inherited, morbidity also may be inherited in a much wider sense than is now held to be the case. The evidence apparently indicates that the decline in the birth rate has not been voluntarily brought about. The author questions whether any artificial measures could possibly have such widespread and synchronous results as the decline in the birth and death rates.

2. Leucocyte Counts in Cirrhosis of the Liver.—L. Rogers states that leucocytosis is common in ordinary cirrhosis of the liver, a high degree of immediate very bad prognostic significance. On the other hand, a marked leucopenia is diagnostic of the disease being secondary to kala-azar. The latter conclusions appear to be of some practical value, as now that operative measures are frequently undertaken in the treatment of cirrhosis of the liver, it is obviously a matter of great importance, if by means of a blood count it should be possible to exclude cases which are likely to prove fatal at an early date, and to confine the surgical procedures to those in which there is a fair chance of permanent benefit resulting.

4. Mercurial Administration.—D. Freshwater concludes that either the intramuscular injection or the inunction treatment is by far the most satisfactory way of treating syphilis and least liable to be followed by relapses. For the ordinary routine treatment of syphilis intramuscular injection is preferable; it is more convenient and cleanly, and does not take much time during the day, but in nervous lesions following on late syphilis—*e.g.* tabes—the inunction treatment is as a rule more satisfactory, the results being sometimes marvelous. Treatment by the mouth should be carried out only when it is not possible to give injections or inunction; it is certainly often useful to give mercury by the mouth between the routine courses of injection. The intravenous method is better left alone except in very severe cases where other means have failed, and in acute lesions of the ophthalmic apparatus where there is danger of loss of sight. Treat-

ment by means of the "mask" is the most satisfactory method of introducing the mercury by respiration; it is certainly very suitable as an alternative method to the oral administration, being cleanly, simple to carry out, and effective. The same applies to the "mercurial bib," but somewhat better results are obtained with the mask; the bib is very suitable for children. Suppositories offer a good alternative method and may be continued off and on for a long time; they are *par excellence* the simplest method of giving mercury secretly when it is necessary. Fumigation is excellent for chronic lesions. The application of a mercurial plaster will often cause a chronic lesion to heal. Baths are somewhat dangerous and unreliable, but may be employed where a syphilitic lesion is complicated with a parasitic one.

5. Vascular Symptoms of Cervical Rib.—T. W. Todd states that in the condition known as cervical rib, any explanation of the vascular phenomena may be found inadequate if it depends only on direct mechanical pressure on the subclavian artery. Clinical and anatomical evidence suggests that the vascular symptoms may be trophic in character and caused by a lesion of the sympathetic fibers in the lower part of the brachial plexus. Certain anatomical facts indicate that damage may occur to the sympathetic fibers to the arm in the situation where a lesion of the spinal fibers is likely to occur in cases of cervical rib. The anatomical disposition of the parts around the subclavian artery as it passes from thorax to axilla indicates that this cannot be the site of injury to the vessel or to sympathetic nerves surrounding it.

8. Industrial Employment of Married Women, the Birth Rate, and the Sex Ratio at Birth.—H. R. Jones has found that the employment of married women in industrial occupations tends to diminish the birth rate. Such employment tends to the birth of a larger proportion of girl infants. Low birth rates tend to the birth of a larger proportion of girl infants. The rate of infantile mortality is higher as the proportion of employed married women rises. The question naturally follows whether the higher mortality is due to the quality of the offspring or to the environment during the year of infancy or to both factors. To answer this requires a more detailed analysis of the causes of death in infancy than is included in the Decennial Report of the Registrar-General, but it is pointed out that the mortality from puerperal fever and childbirth is higher in the textile than in the non-textile districts or in the colliery districts, being 6.74 against 5.12, respectively, and therefore the quality of the offspring is likely to have suffered. Lastly, the author calls attention to the relative influence which the birth rate and the rate of infantile mortality exert on the number of survivors. With a low birth rate and a low rate of infantile mortality the number of survivors out of 1000 infants born is greater than if a high birth rate and a high rate of infantile mortality prevails. But if the survivors out of the number of births per 10,000 inhabitants be calculated, it is found that the number of survivors is greater with a high birth rate and a high rate of infantile mortality than with a low birth rate and a low rate of infantile mortality.

1. Acne and Seborrhea.—A. Whitfield outlines the following treatment of the seborrhea: Attention to the digestion and general hygiene and a diet low in those substances which have an action in increasing secretion. The use of the *x*-rays as causing temporary suspension of sebaceous activity. The use of caustics such as sulphur (probably acting as sulphuric acid), acids (acetic and hydrochloric), strong alkalis, and soft soap. The treatment of the comedo includes mechanical extrusion, the *x*-rays, and the use of microbacillus vaccines. The treatment of the suppuration includes surgical procedures, antiseptics as ointments or fomentations, and the use of staphylococcus vaccines.

9. Chronic and Recurrent Diseases of the Skin in Relation to Heart Disease.—D. Walsh notes that a large number of chronic and recurrent skin eruptions are associated with disease of the heart. Unsuspected organic heart trouble is comparatively common among patients attending a skin hospital. Prognosis in skin diseases largely depends on the state of the heart. Attention to the circulation is imperatively demanded in a large number of skin affections. The success or failure of much of skin therapeusis depends on the attention paid to the circulation. The circulatory inadequacy which determines the onset and duration of many chronic or recurrent skin eruptions might likewise affect internal organs. What is called "idiosyncrasy" might in many cases simply describe a pathological reaction, natural or acquired, to moderate traumatism. In this way the irregular incidence of trade and of drug eruptions might in many cases be explained —predisposition simply being another name for central cardiac inadequacy and disturbed balance of capillary circulation. In all cases of delayed healing or of chronic skin disease the state of the circulation should be carefully investigated. When it is proposed to administer any drug, such as mercury or arsenic, known to act as an organic irritant, the possession of a normal or a fully compensated central circulation should be regarded as a *sine quâ non*. The delayed healing of wounds and the persistence of inflammatory conditions, external or internal, often afford a clinical test of cardiac inadequacy more delicate than the shortness of breath, palpitation, and other ordinary evidence described in the textbooks. The dermatologist who wishes to do justice to himself and to his patients, Walsh says, will have to keep a constant eye upon the heart and its treatment in relation to diseases of the skin.

10. Diseases of the Nails.—G. N. Meachen submits the following conclusions with regard to nail diseases: It is difficult to work up an enthusiasm for a comparatively unimportant section of a special branch of medicine; nevertheless, onychology as a sub-branch of dermatology is worthy of the serious and earnest attention of those interested in the latter subject. In every case of skin disease presenting itself for treatment, either at hospital or in private practice, the condition of the nails should be briefly noted at the time of the examination. Were this carried out systematically in every instance, not only would abnormalities of a most interesting description be frequently found, but also many signs of cutaneous and systemic disease would be discovered. In the great majority of cases of nail disease it is possible to diagnose the morbid condition from careful inspection alone. Two general principles enunciated by the author—the "law of symmetry" and the "law of diminishing intensity"—are applicable in all cases of nail disease except those due to injury or parasitic causes.

Berliner klinische Wochenschrift.

July 29 and August 5, 1912.

Etiology of Malignant Granuloma.—By this term O. and K. Meyer refer to pseudoleucemia, so-called. Hodgkin's disease is also a convenient designation. The authors have been making some very radical studies in the etiology of the same. It was necessary to find typical cases free from all suspicion of tuberculosis. A young woman aged twenty had been ailing for four years with anemia and enlarged cervical glands, and subsequent implication of the glands of the axillæ and groins. Death took place from marasmus. There had not been at any time bacilli in the sputum, although clinically there were thoracic symptoms and fever. Autopsy revealed lymphoid tumors in the lungs and the type of spleen found in Hodgkin's disease. After the histological examination other lesions were reported showing a very extensive infectious process. The lesions were typical of the disease, and the most sensitive tests failed to disclose the presence of tubercle bacilli. A pulp was now made of some of the tumors and animals of several species were inoculated. Structural alterations followed, which while slight in character were similar in part to those of malignant granuloma. The liver contained nodules, while lymphnodes and spleen showed enlargement. In some animals the results were negative throughout. The results were on the whole unsatisfactory and the experiments were repeated with matter from a second patient. In this series all the animals inoculated gave positive results which were pronounced quite conclusive. The fact remained, however, that two of the three animals inoculated died of generalized tuberculosis, the natural inference being that a small focus of the latter had become activated by the artificial granulomatosis. The same association has been encountered before. The Gram-positive bacilli and granules believed to be characteristic of malignant granuloma were obtained in pure cultures, but these later appeared to represent a strain of tubercle bacilli which had undergone some unknown modification. Hence either the tubercle bacillus is the actual cause of malignant granuloma or some unknown, not yet isolated microorganism accompanies it through its cultural life. In any case a pure granulomatosis is able to set up miliary tuberculosis which cannot be set down to mere accidental coincidence.

Mutation and Adaptation in Microorganisms.—Pringsheim discusses the possible changes from the acclimation of high temperatures, as suggested by Dallinger's work with flagellates, the latter, used to 16° C., being adapted through years of effort to 70° C. After this adaptation they were killed by the original temperature. A second type of adaptation is the toxic. Ehrlich found this extremely difficult, his work being done with trypanosomes. It has been effected for a number of species of microorganisms. Once secured it may be transmitted intact through many generations. Naturally, this problem involves the whole of acquired immunity. A third mode of adaptation is to a diminished oxygen supply, this naturally involving the change from aërobes to anaërobes. Adaptation to nutrient media is, of course, well known. The question now arises, do adaptations produce other variations? But to study variability it should be advantageous to isolate organisms who most exhibit departures from the standard. This has been known by Barber, using a special refinement of method, which would be very difficult for routine use. The author believes that research along this line had better be directed for the present to variations in nutrient media. In regard to the practitioner whose interest lies in the pathogenicity of a given germ and not in purely biologic aspects, the author states that virulence variation is at present a subject not adapted to purely scientific research. We must first have more exact information about microorganisms in general.

Treatment of Bacterial Infections with Chemicals.—Blumenthal alludes to the former belief that a chemotherapeutic remedy should be able to kill its bacteria *in vitro*, although atoxyl, the supposed prototype of such a remedy, had no action *in vitro* upon typanosomes. It then became evident that the remedial efficacy of some substances can be explained only through the fact that somehow they mobilize defensive substances. This view is further strengthened by the discovery that a given substance may have a chemotherapeutic action in one kind of animal, yet be inert in another. If mercury were a newly discovered substance and were being tested on animal disease, there could be nothing in the results to warrant a belief that mercurials can cure human syphilis. Recent studies have shown that atoxyl and salvarsan increase the amount of agglutinins, and this indirect action reinforces any direct action upon the microorganisms themselves, for it is of course beyond doubt that a direct action is exerted upon them. This is apparent in contrast to the action of mercurials in syphilis. Long after the remedy has been mostly eliminated the chancre is still alive with spirochetes. The remedial property of mercurials is indirect then, but none the less specific and chemotherapeutic. It is now known that all the efficacious preparations of mercury are fixed in the liver, while inert combinations are not; hence the drug acts somehow by grace of the liver. The rousing of the defensive forces naturally touches upon opsonotherapy, although the author is dealing here with specific chemotherapy.

Intraarterial Therapy.—Bleichroder, Löb and Unger discuss this subject from separate viewpoints. The first-named caused collargol to be thrown into the femoral artery in cases of puerperal sepsis in which the infection was later found to have passed beyond the uterus. In but one case was any favorable action noted, nor was any expected save in the contingency that the infection was still limited to the uterus. The author also considers the possibility of throwing tetanus antitoxin into the carotid artery during compression of the jugulars. This would saturate the brain with the remedy and perhaps be superior to trephining and injecting. Unger discusses systematic animal experimentation with certain injections, as in arterial anesthesia. Löb gives the technique.

Oxaluria.—Rosenberg states that we are still ignorant of the causation of this phenomenon, aside from the exogenous type, and that is not entirely clear, for the alkaline secretions of the intestine should render oxalic acid insoluble. In endogenous oxaluria, the acid could be formed from the glycocoll derived in turn from the gelatine of connective tissues, the nucleiniferous substances, the carbohydrates, glycuronic acid, etc. A study of individual cases of oxaluria may throw light on the mechanism of the single case. For example, a patient with oxalic acid calculus was subject to chronic diarrhea, due evidently to enteritis, in which the reaction of the stools was acid. This pointed to exogenous oxaluria, but the patient ate hardly any vegetables. After a ten-day period of unchecked diarrhea, a new attack of renal colic occurred. Then with a period of alternating constipation oxalic acid disappeared from the urine; not only in this but in another patient as well the author has seen acid diarrhea followed by oxaluria. But how explain this phenomenon? The oxaluria was endogenous, yet must have come about from changes in the food in the alimentary canal. No such etiology has ever been recognized absolutely, although Minkowski once suggested such an occurrence.

Deutsche medizinische Wochenschrift.

August 1 and 8, 1912.

Medicines and Poisons.—Professor Traube first mentions the common assumption of the necessity of a chemi-

cal reaction to explain the action of a remedy or a poison. In recent years the development of the new physical chemistry has shown that purely physical laws also have to be reckoned with in this connection. In certain cases the latter are clearly sufficient for fixing the rationale. This is true of certain remedies which produce blood changes, so that a law may be enunciated as follows: in the blood and in other colloid systems the toxins which are causing diseases are detoxicated when their colloid particles are enlarged. These molecular changes may be ultramicroscopic, microscopic, or macroscopic. From this point of view an antitoxin simply produces its effects by enlarging the colloid particles. The larger the latter, the less the toxicity. The physical theory serves to illuminate already many puzzling features in pharmacodynamics. It shows why in this field one and one do not necessarily make two. Two half doses in succession are often stronger than a single dose because the concentration enters into the reaction. The optimum action of drugs is explained, also that of agglutination and hemolysis. The reenforcing effects upon one another of synergists (Bürgi) is also illuminated, also the frequently noted fact that a certain drug acts better when given in connection with another which is not a true synergist.

Mutations of Bacteria.—Baerthlein reports further upon this subject, upon which he has long been employed. He has developed mutation strains of the prodigiosus by growing on special media and propagating special colony forms. The new strains showed special coloration, although the stock culture was colorless. He also succeeded in producing new colony types of the pyocyaneus, both moist and dry, further showing color mutations. The golden staphylococcus was grown white and in propagation remained white. Conversely he produced the golden staphylococcus from the white. He does not go so far as to assert that he actually transforms the species, but simply produced mutations closely resembling them, although still showing individuality in the colony. Apparently he had little trouble in producing mutations of many germs. With some mutations differences in virulence were also obtained, but this field of work is evidently a matter for the future, although much work has been done already in this field, for example, in the hemolytic activity of different strains of streptococci. A solid foundation concerning the various mutants produced must underlie a study of the pathogenicity.

Epidemic of Jaundice.—Weissenberg describes an epidemic in Southern Russia. Only a certain number of these episodes are entitled to the name of Weil's disease; the latter is severe and often fatal in character. In the present epidemic there were forty-four victims. It began in the summer and lasted for a year and a half, the victims being urban residents. The affection was decidedly mild and as a rule the patients were not laid up. In a certain number there was considerable enlargement of the liver and albuminuria. One fatality from acute yellow atrophy occurring during the epidemic may have been a coincidence. In the absence of autopsies or bacteriological examinations, no data can be advanced to throw light on the intimate nature of the disease, which was in part an ordinary acute catarrhal jaundice of epidemic incidence.

Oxygen Poisoning.—Bornstein and Stroink refer to the consequences of breathing compressed air and of employing oxygen inhalations as a prophylactic before compression or before decompression. The English authorities have taught that compressed oxygen is a strong poison, able to kill animals amid convulsions. The contrary was claimed many years ago and has been confirmed in part in recent years. The authors have had a chance to study a mild case of true oxygen poisoning in one of their own persons. Bornstein had inhaled oxygen while in two atmospheres of air up to forty-eight minutes with impunity on many occasions. On a particular occasion he began to inhale oxygen while working in compressed air and at the fifty-first minute noticed contractions in the right lower extremity. In the course of a minute the left limb was similarly affected. Having determined the low limit of oxygen toxicity the experiment was broken off. Animal experiment also shows abundantly that respiration of oxygen in a compressed atmosphere has toxic consequences.

Spread of Typhoid.—Brückner on a basis of his personal studies of epidemics comes to the following conclusions: Koch's teaching that the subject who gives off bacteria is solely responsible for spreading the disease has received the most completee confirmation. In tracing the spread of an epidemic we always see the characteristic uncleanliness and filth which surrounds patients and carriers. This not only renders the immediate neighborhood dangerous to others, but more remote neighborhoods through contamination of food supplies. Contact infection plays a minor rôle. Destruction of the bacilli in the feces and urine is the principal reliance; next comes the inculcation of cleanliness and strict supervision of milk and other food supplies. All carriers ought to be found, controlled, and sterilized.

Adrenal Therapy in Addison's Disease.—Klein relates the case of a powerful man who without apparent cause developed typical Addison's disease within a few months. The picture comprised loss of weight, pigmentation, a general collapsed appearance, and great muscular weakness. This was followed by marked gastroenteric disturbance of a sort well calculated to end his life from inanition. His weight had come down from 186 to 95 pounds. None of the remedial measures used were of the least avail. He was then placed upon fresh adrenal glands from the sheep, taking them raw and minced. As he developed repugnance to these a compressed extract was substituted. The improvement was striking, all the symptoms showing change for the better. The treatment was suspended at times, but if for more than two weeks always with detriment. He had recovered fifty pounds of his weight, and his improvement otherwise was harmonious, when suddenly and without apparent cause acute gastritis set in, with prostration. There was no evidence of a return of the disease. It was learned, however, that he had suspended his adrenal treatment for over three weeks. His stomach was now unable to retain anything. Cerebral symptoms now set in and death took place from coma. The lesson of this case is that we have not sufficiently tested organotherapy in these cases. Others have obtained equally favorable results, and the best evidence of the efficacy is the aggravation of these cases when the treatment is suspended.

Tertiary Specific Ulceration of the Pharynx Undergoing Malignant Transformation.—D. McKenzie reports the case of a man, aged eighty-one years, whose throat had been troubling him for three months. The syphilitic element was still active; it had destroyed the uvula and much of the soft palate, and had eroded the tissues in the tonsillar regions. In the region of the left tonsil a raised area, rather nodular in appearance and hard to the feel, made the author ssupect the existence of malignancy. The nodule was therefore removed and examined for malignancy, with a positive result. There was a small, hard gland under the left angle of the jaw. The Wassermann reaction was negative. The patient was given iodide of potassium and had already benefited by it. The occurrence of epithelioma in the midst of what seemed to be an active tertiary ulceration was an interesting clinical experience.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SHOULD NON-ORGANIC HEART MURMURS BE REPORTED?

To the Editor of the Insurance Department:

Sir:—I have noted your articles in the Medical Record with interest and have felt that they would prove of considerable value. I must, however, take exception to some of the statements concerning non-organic murmurs in the issue of June 29, 1912. We agree that an examiner should satisfy himself as thoroughly as possible whether a murmur is or is not organic, and the company must be given the benefit of the doubt, but we do not agree that an examiner, if convinced that the accidental sound is not significant of a pathological lesion, should not report it. An examiner should report his findings just as they are and he can further express his opinion on findings, but the Home Office Medical Department is responsible for the estimation of the effect the conditions found have with the rating of the risk.

I am under the impression that the statements made in this issue of June 29 will, in some respects, produce an undesirable result, leading some examiners to give the home office their opinion of their findings and not record what they may hear. Please let us have a statement from you as to the opinions we have expressed above.

J. Allen Patton, M.D.
Assistant Medical Director the Prudential Insurance Company.

Before discussing the question we desire to thank Dr. Patton for bringing up this point. It gives us an opportunity to supplement our views, as there may be others who have the same feeling in regard to the statements in the article referred to by Dr. Patton.

Medical directors are generally too busy to afford the time so often exacted in clearing up those statements by examiners which, while they apparently convey no significance, must nevertheless be further explained on the ground that anything which is important enough to incorporate in the report is of sufficient consequence to call for investigation until all doubt is removed. In other words, the reporting of some unimportant abnormality or of some trivial or extraneous matter with positively no underlying diseased condition and, consequently, no bearing upon the insurability of the risk, only serves to increase uselessly the work of the home office staff. A non-organic murmur does not affect the acceptance of a risk any more than one of the well-known physiological differences in auscultation and percussion between the two sides of many healthy chests or some anomaly of the radial artery. It is our belief that while examiners are being taught to be rigidly careful in their search for pathological conditions, they should also be encouraged to refrain from clouding up their reports by references to inconsequential matters.

In the case that an examiner does report a non-organic murmur, after heeding the strict injunctions in the article referred to (it would be well for examiners reading these lines to consult the article), the responsibility of the home office medical department ends when after more or less correspondence it is found that the examiner holds to his opinion, for, after all, he must be relied upon and his findings must be accepted if he is worthy of the position he holds. A medical director would naturally choose to have his own ear to the chest when estimating the value of a risk, since he assumes the final responsibility in accepting it, but this proceeding can be resorted to only in the extremely small percentage of cases which come under his personal observation.

We hold to the view that the medical department of every company should maintain so high a standard of efficiency among its examining force that the opinions of its field examiners may be depended upon. The medical profession have to admit that the membership includes men of all grades of efficiency from excellent to poor. Knowing this, the medical department should maintain a continuous effort to weed out the incompetent and unreliable, by replacing them by some of the better equipped men found in almost every community. The writer can speak with authority on this subject and claims without hesitation that an organization of this degree of excellence can be built up, the company which he represents having succeeded in this direction after years of hard and persistent work. There is no reason to doubt that Dr. Patton's company has undertaken this task with an equally satisfactory return and that he may exercise the same readiness to accept the reports of the examiners.—Editor.

The Medical Department Organization and Method of Procedure.—H. A. Hoppe says there is a dual function to be exercised in the acceptance of risks. The one, purely advisory, is controlled by the medical director; the other, executive in its nature, belongs to the approving officer who passes on the cases submitted. It is necessary that these two officials work hand in hand, for only by the freest exchange of opinions can the work be successfully accomplished. Hoff thinks that there is no valid reason why the doctrine of scientific management should not be as successfully applied in the medical department of a life insurance company as the now classic example of the handling of pig iron in the Bethlehem steel plant. Refering to death-loss records, the explanation is given that this is a record of death losses by examiners, giving all essential details and bringing together all losses which have occurred among cases examined by any one examiner.

According to Hoff, one of the most trying features of the work in the Medical Department is the frequency with which agents will employ unauthorized examiners. Many and varied are the explanations advanced in support of such action, but it will be found a paying proposition never to accept such explanations without thorough investigation.

In conclusion it is stated that the scheme of organization outlined by Hoff is based on the following considerations: 1. That the ultimate object of all activities in the medical department is the attainment of a favorable mortality experience. 2. That the means by which this can be secured is a careful selection of risks and an effective control of medical examiners. 3. That one of the principal duties of the department is to so arrange the machinery as to serve adequately, promptly, and easily the interests of the men in the field. 4. That this desideratum can be best secured by bringing together under one responsible control all activities relating to the consideration of risks.—*Second Mid-Year Meeting of the American Life Convention*, February 28, 29; March 1, 1912.

Book Reviews.

An Index of Differential Diagnosis of Main Symptoms. By Various Writers. Edited by Herbert French, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), Assistant Physician in Guy's Hospital. With sixteen colored plates and over two hundred illustrations in the text. Price $8.00. New York: William Wood & Company, 1912.

This work is a new departure in medical literature and is in a sense a corollary to the index of treatment written after the same general plan. The title "index" is not absolutely accurate, for while it is true that the articles are arranged in alphabetical order those on the more important symptoms are really well and carefully written monographs in which differential diagnosis is dealt with. There has long been felt a want for a work of this description, and in editing this volume Dr. French has fulfilled the object at which he has aimed with remarkable painstaking care and ability. This guiding principle has been to suppose that a particular symptom attracts special notice in a given case, and that the diagnosis has to be established by differentiating between the various diseases to which the symptom may be due. As may be easily understood in editing and compiling a work of this sort one of the chief difficulties met has been as to where to draw the line with respect to symptoms themselves. However, this difficulty has been solved in a satisfactory manner. There are a few omissions in the book, that is, there are a few subjects which would seem to have been worthy of discussion at some length. Still it must be borne in mind that if bacteriological and pathological tests had been included the size of the book would have been increased to such an extent as to have made it unwieldy. In its present form the volume covers the entire range of medicine, gynecology, ophthalmology, dermatology, and neurology, and for an initial effort in the particular direction of differential diagnosis must be esteemed wonderfully complete. The general index itself is commendably full, covering some 167 pages. Whilst the body of the book deals with symptoms, the general index collects these under the headings of the various diseases in which they occur. Moreover, those minor symptoms and physical signs which have not been thought of sufficient importance to merit separate articles will be found in the general index. The plates and illustrations are good and the list of contributors should be a guarantee that the subject matter is treated both from a medical and literary standpoint with knowledge and ability. No medical book brought out in recent years has been so well adapted to the use of the busy general practitioner, and Dr. French is to be congratulated on the acumen he has displayed in adventuring into hitherto untrodden fields.

The Edward Bok Books of Self-Knowledge for Young People and Parents. How Shall I Tell My Child? by Mrs. Woodallen Chapman; When a Boy Becomes a Man, by H. Bisseker; Instead of "Wild Oats," by Winfield Scott Hall. Price 25 cents each. New York, Chicago, Toronto: Fleming H. Revell Company, 1912.

The vexed question of how and when to discuss the facts of the sex life with the young is *so* vexed that it is often pusillanimously evaded by the very people whose duty it is to meet it frankly and with courage. These well turned out and convenient little text books on the subject, which we are told are to be followed by others, meet most admirably the needs of all those, and they are many, who crave wise words of guidance on the subject. The first of the series, "How Shall I Tell My Child?" is written for the parent, and would seem to answer the question adequately for us all; the others are written to be placed immediately in the hands of the youth (the second for the boy, the third for the young man) and are, like the first, little masterpieces of clean, straightforward frankness.

Primary Malignant Growths of the Lungs and Bronchi. A Pathological and Clinical Study. By I. Adler, A.M., M.D., Professor Emeritus at the New York Polyclinic, Consulting Physician to the German, Beth-Israel, Har Moriah, and People's Hospitals, and Montefiore Home and Hospital. Price, $4.00 net. New York: Longmans, Green & Company, 1912.

This little monograph on tumors of the lung is a gratifying evidence of the increased interest in pathology in this country. The author, well known as a clinician of ability and scientific training, has for years been interested in tumors of the lung, bronchi, and mediastinum, and has collected the results of his observations in a volume devoted to his teacher, Prof. Dr. Julius Arnold. The actual text occupies 109 pages, being divided into introductory and historical portions, a section on the influence of tuberculosis and other conditions on the production of malignant tumors, chapters on morphology, and finally a clinical discussion of symptoms and surgical treatment. The pathological portion is admirably illustrated with a series of sixteen photogravures showing the gross and microscopical appearances of the lung tumors. The remaining 215 pages are devoted to a tabular report of all the known cases of primary malignant tumors of the lung. The volume is unquestionably the most important treatise on this special subject.

Manuel d'Histologie Pathologique. Par V. Cornil, professeur à la Faculté de Médecine, membre de l'Académie de médecine, médecin de l'Hôtel-Dieu, et L. Ranvier, professeur au Collège de France, membre de l'Institut, membre de l'Académie de médecine, avec la collaboration de MM. A. Brault, membre de l'Académie de médecine, médecin de l'hôpital Lariboisière, ancien chef des travaux pratiques d'anatomie pathologique à la Faculté de médecine, et M. Letulle, professeur à la Faculté de médecine, membre de l'Académie de médecine, médecin de l'hôpital Boucicault. Troisième édition. Tome quatrième. G. Millian, Poumon.—L. Decloux et L. Ribadeau-Dumas, Bouche, Pharynx, Osophage.—D. Critzman, Estomac.—L. Decloux et L. Ribadeau-Dumas, Intestin, Colon, Rectum.—A. Brault et Th. Legry, Foie.—Klippel et Lefas, Pancréas.—A. Brault et A. Courcoux, Rien.—N. Hallé, Appareil Urinaire. Avec 438 gravures en noir et en couloures dans le texte. Price, 45 francs. Paris: Librairie Félix Alcan, 1912.

In the third edition of Cornil and Ranvier's manual of pathology, the fourth volume of which is devoted to the gastrointestinal tract, liver, pancreas, and genitourinary region, a good many improvements and additions have been made which render the work a valuable repository of pathological anatomy, though the point of view is, as possibly it should be, predominantly that of the French school. The quotations from German and English writers are more noticeable for their infrequency than for any other reason. Yet in this way the book retains a certain personal quality and novelty which is refreshing to those who spend their time in reading the German pathological works. The only possible criticism is of the inferior quality of many of the cuts, which by their crudeness and poor printing do not reflect much credit on the present French school of illustrators who have departed sadly from the high standard set in the illustrations of the famous tomes of the old French anatomists.

Die Prostatahypertrophie. Ihre Pathologie und Therapie. Für Ärzte und Studierende dargestellt von Dr. Med. Wilhelm Karo, Berlin. Price 1.60 marks. Berlin: Oscar Coblentz, 1912.

This is a pamphlet of fifty pages giving a good résumé of the pathology and therapy of prostatic hypertrophy. It is well written but contains nothing original.

Massage and the Swedish Movements. Their application to various diseases of the body. Lectures before the Training Schools for Nurses. . . . By Kurre W. Ostrom, from the Royal University of Upsala, Sweden. Seventh edition, revised and enlarged. With one hundred and fifteen illustrations. Price $1.00. Philadelphia: P. Blakiston's Son & Co., 1912.

This small book consists of a clear and conservative presentation of the technique of massage and the results that can be obtained by it and by well-regulated gymnastic exercises. The author lays stress throughout on the necessity of a physician's supervision over the work of the masseur. The book should prove valuable to nurses, to masseurs, and to physicians. Its usefulness is proved by the calls for a seventh edition.

Manual of Surgery. By Alexis Thomson, F.R.C.S. Ed., Professor of Surgery University of Edinburgh; Surgeon Edinburgh Royal Infirmary, and Alexander Miles, Surgeon Edinburgh Royal Infirmary. Volume III. Operative Surgery, with 220 Illustrations. Price $3.50. Edinburgh, Glasgow and London, 1912.

This compact volume is the third of the excellent series on surgery by two distinguished Edinburgh surgeons. The Edinburgh medical school not long ago enjoyed a far-famed reputation for the thoroughness of its teaching and the series referred to and this work in particular well maintain this high standard. In concise but adequate language the writers describe operative surgical measures as they are practised to-day, modified to some extent by the cautious conservatism of Scotch and English surgeons. The volume contains a large number of fine illustrations, and from all points of view may be strongly recommended as a textbook for advanced students and as a reference book of value for the surgeon and general practitioner.

Special Article.

A REPORT UPON THE HEALTH CONDITIONS IN THE PUBLIC SCHOOLS OF NEW YORK CITY.[1]

BY THE COMMITTEE ON PUBLIC HEALTH HOSPITALS, AND BUDGET OF THE NEW YORK ACADEMY OF MEDICINE.

Objects of the Report.—This study of health conditions in the public schools has been carried on with the following main objects in view:

1. To summarize the present methods of safeguarding the health of school children employed by the Department of Health and the Department of Education.

2. To analyze these methods and their results from a strictly medical point of view.

3. To enlist the interest and cooperation of the medical profession as a whole in the problem of school hygiene.

4. To give medical advice and assistance to the Departments of Health and Education in their efforts to solve these problems.

5. To support the reasonable demands of these Departments for sufficient city funds to maintain proper health conditions in the public schools.

It is desired to make this report, upon the one hand, educational to the general medical profession, and upon the other, helpful to the two departments of the city government which are mainly concerned.

It is inevitable that such a study should contain criticism. We have attempted to offer such criticism in a spirit of helpful suggestion rather than of indiscriminate faultfinding. This attitude has been the more easy to maintain for the reason that our study has mainly impressed us with the magnitude and complexity of the problem, and with an appreciation that both departments have been making earnest efforts to solve it, in spite of very little outside interest or support.

No body of citizens should be more concerned in matters of school hygiene than physicians, yet none has been more remiss in evincing an interest in them.

Definition of Medical Inspection of School Children and Its Purpose.—Efficient medical inspection includes a complete and detailed physical and mental examination of every child in the school. The purpose of such inspection is: First, to conserve the health of the children, and second, to afford them physical comfort—two indispensable conditions of proper education.

Extent of Its Adoption.—Medical inspection in schools was first made compulsory in Austria in 1873, and was subsequently adopted in Sweden, Argentina, Hungary, Norway, Switzerland, Servia, France, Japan, Roumania, Russia (1899) and Great Britain (1907). In Germany and in the United States it is done locally and is not compulsory.[2] According to the report of the Child Hygiene Department of the Russell Sage Foundation of 1911, 1038 cities in the United States had medical school inspection.

Reasons for Its Wide Introduction.—The justification of medical examination lies in the fact that large numbers of school children are found to be suffering from physical defects of one kind or another, and that these defects hinder the progress of the child in its growth and in its studies.

PHYSICAL EXAMINATION FOR NON-CONTAGIOUS DEFECTS.

Number examined	1911 230,243		1910 266,426		1909 231,081	
	Found Defective	Per Cent.	Found Defective	Per Cent.	Found Defective	Per Cent.
Needing treatment	166,368	72.2	196,664	73.8	172,112	74.4
Found with defects other than teeth alone	75,857	32.9	101,602	38.1	102,150	44.2
With defects of teeth as only defect	90,511	39.3	95,062	35.6	69,962	30.2
With defective vision	24,514	10.6	29,634	11.1	30,408	13.1
With defective hearing	1,491	.6	1,519	.5	2,340	1.0
With defective nasal breathing	27,316	11.8	40,946	15.3	43,393	18.7
With hypertrophied tonsils	34,639	15.0	50,012	18.7	50,934	22.0
With defective nutrition	5,845	2.5	8,691	3.2	7,249	3.1
With pulmonary disease	483	.2	656	.2	744	.3
With cardiac disease	1,661	.7	2,370	.8	1,503	.6
With orthopedic defects	1,190	.5	1,683	.5	1,461	.6
With chorea	861	.3	951	.6	940	.4
With defective teeth	135,843	58.1	164,250	61.6	131,747	57.0
With defective palate	85	....	153	....	324	.1
With tuberculous lymph nodes	418	.2	759	.2	810	.3
Reported treated[4]	65,150	86.0	64,861	64.0	84,968	83.0

[4]These figures do not include children reported with defective teeth as the only defect, whose treatment consisted only of instruction in oral hygiene.

Statistics of Defects Found in New York Public School Children.—Of the total number of 231,081 school children examined for non-contagious defects in 1909, 172,112, or 74.4 per cent., were found to be needing treatment. About 60 per cent. of children suffer from bad teeth, 33 per cent. from defects other than teeth alone, 12 per cent. from defective nasal breathing, 15 per cent. have hypertrophied tonsils, etc., as seen from the accompanying table.[3]

Children Suffering from Communicable Diseases of Eye and Skin.—Of a total of 674,667 children in public schools, 286,591, or 42 per cent., were found suffering from communicable eye and skin diseases in 1910. More than a half are pediculosis cases, and 16 per cent. trachoma.

The following is a table (from records of the Health Department) showing distribution of these cases by diseases for the years 1909-1911.

COMMUNICABLE DISEASES OF THE EYES AND SKIN.

Year	Trachoma	Conjunctivitis	Ringworm	Impetigo	Scabies	Favus	Pediculosis	Molluscum Contagiosum	Miscellaneous	Total
1909	45,615	49,807	7,788	12,516	4,006	409	151,585	154	14,621	286,591
1910	20,888	26,855	9,052	2,251	.....	290	153,797	143	41,660	263,828
1911	15,245	25,941	4,083	7,713	1,768	220	152,045	96	11,660	248,771

Elements of the Health Conditions in Public Schools.—The health work in the schools consists in:

1. Medical examination of school children for contagious and non-contagious defects.
2. The elimination of children found suffering from contagious diseases.
3. Calling of parents' attention to the defects of their children.
4. Direction of children to physicians and dispensaries.
5. Following the children up to see whether they received treatment.
6. Treatment in schools.
7. Instruction in personal hygiene.
8. Physical training instruction.
9. Segregation of backward and mentally defective children.
10. Sanitary care of schools.

[1]This report has been prepared by E. H. Lewinski-Corwin, Ph.D., Executive Secretary of the Committee, and has been closely supervised and edited by members of the Committee, who are also responsible for the summary and recommendations: Dr. Charles L. Dana, Chairman; Dr. James Alex. Miller, Secretary; Dr. Algernon T. Bristow, Dr. Haven Emerson, Dr. Arpad G. Gerster, Dr. S. S. Goldwater, Dr. Thomas W. Hastings, Dr. L. Emmett Holt, Dr. John H. Huddleston, Dr. Abraham Jacobi, Dr. Theodore C. Janeway, Dr. Egbert Le Fevre, Dr. Samuel Lloyd, Dr. Frank S. Meara, Dr. W. Gilman Thompson, Dr. Linsly R. Williams, Dr. Philip Van Ingen.

[2]Dr. A. P. Knight, in "Publication" No. 4, issued by the Medical Faculty of Queens University, Kingston, Ontario.

[3]Monthly Bulletin of the Dept. of Health for April, 1912, p. 101.

The administration of the school health work, as outlined, is in this city, as in almost all of the larger American cities, carried on by the Department of Health and the Department of Education jointly, the work of one, however, not overlapping the work of the other.

1. *The Bureau of Child Hygiene: Its Duties.*—The work which the Health Department does in this connection is under the care of the Division of Child Hygiene, created in August, 1908. Medical inspection and examination of school children is only one of the multifarious duties of the Division. At the present time the activities of the Division in addition to medical inspection of school children are:

1. The control and supervision of midwives.
2. The reduction of infant mortality.
3. The supervision of foundling babies boarded out in homes.
4. The inspection of institutions harboring dependent children.
5. Inspection and sanitary supervision of day nurseries.
6. The enforcement of that part of the Child Labor Law which relates to the issuing of employment certificates.
7. The vaccination of school children.

Organization of the Division of Medical School Inspection.—The organization for the medical inspection of school children is as follows: Director, 1 assistant director, 5 borough chiefs, 15 supervising inspectors, 76 school medical inspectors, 1 superintendent of nurses, and 172 nurses. The duties of the director, the assistant director, the borough chiefs and the superintendent of nurses are not confined to school work exclusively.

The Bureau of Municipal Research criticized the dual system of supervision—one for physicians and one for nurses, as carried on up to Jan. 1, 1912.[1] Since Jan. 1, 1912, the nurses and their supervisor have been under the direction of the Supervisor of Inspectors, in whom all responsibility is centered.

Statistics of the Work of the School Physicians.—For purposes of school medical inspection, the Bureau of Child Hygiene has divided the city into 76 districts, the size of which is based on the number of children in the schools. One medical inspector is assigned to duty in each district. Where the schools are smaller, more of them are found in one district. In Manhattan, Bronx and Brooklyn the number of schools to every inspector averages from 4 to 5, in Richmond the average is 10, and in Queens it is 13. The average number of children to each inspector varies from eight to nine thousand in Brooklyn and Queens and about four thousand in Richmond.

Amount of Time and Work Required of Each Inspector.—There is no definite daily amount of time or work required of the inspectors. On the average, however, they work from 3 to 4 hours daily. They are not required to make a definite number of examinations a day, but they average from 20 to 22 a day each. The frequency of visits to one school depends on the number of schools assigned to each inspector, and how widely the schools are separated from each other. The inspector spends two days in each school in rotation.

Frequency of Examinations.—Each child is examined upon entering school and again before graduation and in addition every two and a half years, on the average, in the interim.

The examinations are made chiefly for the various non-contagious or more or less chronic physical defects of the eye, ear, throat, nose, heart, lungs, and joints. The child's clothing is not removed at the examination. One of the reasons for this, given by the New York Department of Health officials is that parents would object to having examinations of girls made by school physicians. Owing to this, as well as to the fact that the length of time allotted to each child is a few minutes at the most, the examinations are not thorough.

Accuracy of Examinations.—How accurate the examinations have been since the formation of the Child Hygiene Division, August 26, 1908, we have no means of telling. In 1908 the Bureau of Municipal Research, in co-operation with the Department of Health, conducted an inquiry into the methods and results of the examinations. It was found then that the inspectors differed widely in the number and kinds of defects found in the same children examined. Discrepancies as great as between 30 and 92 per cent. and between 43 per cent. and 84 per cent. occurred in the same schools, while the variation in percentages found defective in the whole of Manhattan was from 100 per cent. to 32 per cent. and from 100 per cent. to 18 per cent. in Brooklyn.[2]

Statistics of the Work of School Nurses.—The nurses' districts are assigned similarly to the physicians' districts, on the basis of school population, and its density. In Manhattan and the Bronx two is the average number of schools assigned to a nurse, three in Brooklyn, seven in Queens and five in Richmond. The average number of children to each nurse is: In Manhattan, 4100; Bronx, 3978; Brooklyn, 3965; Queens, 3902; Richmond, 1878; New York City, as a whole, 3968.

The nurses are on duty from 9 to 4 every day with an hour off for lunch, their working day thus being six hours. They make routine examinations, recommend children for exclusion, notify the parents of the defects of their children, instruct the children in personal hygiene, treat minor skin diseases, and follow up cases in the homes.

Details of the Nurses' Work.—1. Exclusion of contagious disease cases. Beginning Jan. 1, 1912, the duty of exclusion of children from school for major and all minor contagions was assigned to the nurse, in accordance with the plan suggested by the Bureau of Municipal Research and tested successfully by the Department of Health, for several months before adoption, in a number of schools.

In the morning the nurse examines all the children referred to her by teachers as suspicious. If she finds any symptoms of a contagious disease she so informs the principal, who excludes the child from the school. In cases of sore throat she takes cultures and excludes the child for a period till the report of the Laboratory is given. If the culture is negative, the child is returned to school, otherwise the case is turned over to the Division of Contagious Diseases. In cases of measles, scarlet fever, chickenpox, whooping cough, erysipelas, mumps, and tuberculosis the nurse, after excluding the child, notifies the school medical inspector, who visits the case at home and makes the diagnosis. From the accompanying table showing the number of exclusions for five corresponding months of last year, and this year, it is evident that nurses exclude more unnecessary cases than physicians. Cases in the Borough of Manhattan are given below, as the complete records for 1911 are available for this borough only.

In cases of scarlet fever 63.8 per cent. of nurses' exclusions were true cases, while 66.6 per cent. were true in cases of physicians'; in measles 56 per cent. were true with nurses and 85 per cent. with physicians; in the case of mumps 78 per cent. were true while 100 per cent. were true with physicians. The small number of true cases of diphtheria on both the physicians' and nurses' diagnoses is due to the fact stated already, that all sore throat cases are excluded. As a rule the nurses are very cautious and exclude all the suspected cases.

The Division of Child Hygiene is of the opinion that the efficiency of nurses in diagnosing contagious diseases

Exclusions From School on Account of Major Contagion.

	January 1 to June 1, Borough of Manhattan					
	1911			1912		
	Total Number of Exclusions	True Cases	Per Cent.	Total Number of Exclusions	True Cases	Per Cent.

[1] Report of Bureau of Municipal Research, September, 1911, p. 17.

[2] Cf. Report of the Bureau of Municipal Research, "A Bureau of Child Hygiene," 1908, p. 11-14.

is probably as high as that of physicians, but that they are much slower in their work. It is, however, impossible to determine accurately the comparative rapidity of the work of physicians and nurses from the data at the disposal of the Division of Child Hygiene. The experiment is too new to warrant any positive opinion on its expediency. The charge made that the contagion bred in the schools this year was due to the fact that nurses were making exclusions cannot be proven nor does it seem at all probable.

2. Routine examination of children.—Each classroom is, on the average, examined once a month by the nurse. Individual instruction in personal hygiene is given to children, and, in cases of communicable eye and skin diseases, notices to parents are sent out informing them of the condition of the child, and asking to have him treated.

3. Treatment of communicable skin diseases.—If no treatment is obtained, and the child's family is too poor to employ a physician, the nurse treats such cases in the school, following a procedure outlined by the Department of Health. A copy of the instructions to nurses in this respect is found in the appendix to this report. As to the efficacy of this measure, the Monthly Bulletin of the Department of Health for April 1, 1912, says (p. 100): "In this connection it is interesting to note, that the employment of nurses for the treatment in the schools of contagious diseases of the eye and skin has resulted in a marked decrease in the number of exclusions necessary. In 1903, 57,665 children were excluded on account of contagious diseases of the eye and skin, while in 1911 it was necessary to exclude 3361."

From the point of view of the scholastic standing of the children and the diminution of truancy, this decrease in exclusions is a distinct gain.

4. Non-contagious defects.—The non-contagious defects are never treated in schools. Nurses are under positive orders from the Department of Health not to give any treatments in non-contagious diseases, except first aid in emergencies. The nurse tells the children what is the nature of their defects as diagnosed by the medical inspector, and advises them to see a physician. If this fails, she sends for the parents and explains the situation to them, or as the last resort, she visits the homes of the children for the same purpose.

5. The follow-up work.—It is the nurse's duty to see that all the defective cases receive treatment and that all the excluded cases are under the care of physicians. This follow-up part of the medical work in the schools is the most important one. Unless the discovered defects are remedied, medical examinations are an unnecessary expense to the community. Much more stress should be laid on the follow-up work than is being done at the present time, owing to the insufficiency of the staff of nurses to do it thoroughly in each case. In view of the great prevalence of defects among the school children, the number of children per nurse is at the present time much too high.

The Cost of Medical Inspection of School Children.—For the year 1911, the costs of the work are given by the Department of Health as follows:

1. The cost of inspection for the detection of contagious diseases amounted to $0.57 per 1000 children inspected.

2. The cost of each physical examination amounted, on an average, to $0.00~ and

3. The cost of the home visits of the nurses averaged as high as $0.60 for each case.

Statistics of the Total Cost of the School Medical Work Comparatively for 1911 and 1912

1911 School Work	
126 medical inspectors @ $1,200 per annum	$151,200
134 nurses @ $900 per annum	120,600
260	$271,800
1912 School Work	
76 medical inspectors @ $1,200 per annum	$91,200
172 nurses @ $900 per annum	154,800
248	
6 additional inspectors, *i.e.*, supervisors @ $1,200 per annum	7,200
10 additional nurses, *i.e.*, supervisors, @ $900 per annum.	9,000
4 medical inspectors (for physical examination of children for employment certificates) @ $1,200 per annum	4,800
	$267,000

Cost of school work year 1911, $271,800; 1912, $267,000; difference, $4,800.

Advantages of the 1912 System Over That of 1911.—1. *Economy.* In 1911 there was a force of 260 nurses and inspectors at a cost of $271,800. In 1912 the force was decreased to 248 (that is, the force of those actually working with the school children), the cost being $267,000. That is, the actual gain in economy is $4,800

2. *Increased number of working hours.*—It was thought that there would be a marked increase in the number of hours given to the work as the number of nurses was increased and they were expected to work seven hours a day, while physicians work only four hours. They actually do work 6¾ hours a day, and the inspectors work 3¾ hours a day, so that the total gain by this substitution proves to be 69 hours a day.

126 x 3¾=472½ hours given by medical inspectors last year.
134 x 6¾=904½ " " " nurses " "
1377 " Total
76 x 3¾= 285 hours given by medical inspectors this year.
172 x 6¾=1161 " " " nurses " "
1446 " Total
1377
69 " a day difference

3. *Increase in physical examinations.*—Under the present system, though the number of inspectors is only 76, the number of inspections made during the first five months of this year was 19,484 larger than it was during the corresponding period of last year with 126 inspectors. The number of physical examinations that the inspectors were able to make this year has been increased from 1169 to 2195 per inspector, which is almost 100% gain.

During 5 months (Jan. 1-June 1), 1911—*i.e.*, in 100 days—126 inspectors made 147,313 inspections, or about 12 a day.

During the same period in 1912, 76 inspectors made 166,797 inspections, or about 20 to 22 a day.

4. *Increase in class inspections.*—The number of inspections of children was 2,244,696 last year and 2,837,038 this year, making a gain of 581,342.

5. *Increase in number of treatments for physical defects received by children owing to stronger pressure by nurses.*—The number of children receiving treatment for physical defects was 74,864 in 1911 and 82,158 in 1912, making a gain of 7,294. The larger number is due to the larger number of nurses.

6. *Increase in total number of home visits by nurses.*—The number of home visits by nurses, which is the most essential part of efficient school work, was, owing to an increase in the staff of nurses, larger by 10,492 cases during the period from January 1 to June 1 of this year than it was during the corresponding period of last year.

	1911	1912
Number of nurses on duty	134	172
Number of home visits	95,919	106,411
Average number of calls to each nurse	715	612

Disadvantages of the 1912 System.—The following is a summary of the reports of four borough chiefs, 15 medical supervisors, and 14 supervising nurses with regard to the present system of medical inspection of school children.

I. *Morning Inspection for Contagious Diseases.*—The reports are unanimous in disapproving of nurses diagnosing and excluding contagious cases, for the following reasons:

(1) Their training has not fitted them for it physically or mentally.

(2) They are overworked and unable, for lack of time, to perform their other duties, especially home visits, which is the essential part of their work. According to the statement of the Board of Health, based on 300 cards selected at random, the amount of time devoted to home visits last year averaged three hours per nurse per day; this year the average is 43 minutes.

(3) There is a duplication of work, because the inspectors have to visit each case excluded.

(4) The nurses exclude many false cases, thereby causing the inspectors to waste much time in making unnecessary visits. From the table on page 9 it can be seen that in 100 days they excluded 1,595 cases, or 16 cases a day, for 150 schools, and in 1912, 17 cases a day for 150 schools, which would seem to take not very much time.

(5) The medical inspector is not able to keep in close touch with the school on account of the infrequency of his visits, so the "school physician" no longer exists and the nurse can not take his place. Principals and parents naturally do not have the same confidence in her judgment that they have in the physician's.

3. *Physical examinations.*—It is claimed that the in-

crease in the number of examinations made under the present system is not as large as was expected. This is attributed to the many interruptions by nurses and principals and to the fatigue of making examinations for three hours at a stretch. This assertion has no basis in statistical facts, which prove that the average number of examinations per inspector has almost doubled.

4. *The follow-up work.*—Although the total number of home visits of nurses has increased, the number of visits per nurse decreased, from 715 during the first five months of last year to 612 during the same period of this year.

5. *Consultations with parents.*—The consultations with parents in schools which the physicians were having and the home visits which, up to January 1, 1912, the physicians were making have been discontinued because it was impossible to carry them on under the present system.

6. *Employment certificates.*—Last year the children wishing to apply for employment certificates were referred by the principal to the school physician for physical examination. Owing to the infrequency of the physician's visits this plan has had to be abandoned and the children referred to the borough office of the department, while extra inspectors have had to be detailed to these offices to perform this work.

7. *Tuberculosis.*—The detection of tuberculosis in school children is a matter of vital importance. Last year the inspectors during their morning and routine inspections found many cases requiring immediate exclusion and care. This year the nurses are overlooking these cases, and in any event are unable to make a diagnosis. The results may be seen in this statement:

Number of cases of tuberculosis excluded from schools in Manhattan, January 1 to June 1, 1911, 142; the same period, 1912, 17.

8. *Clerical work.*—In all the reports there are complaints about the time taken for keeping records, and special bitterness is shown against the copying of the health record of the child, which is kept on file by the nurse in the school and copied by her on the class card—an absolutely unnecessary work. The class card goes with the child to different schools and is always on file in the nurse's office.

Cooperation of Parents.—The cooperation of parents in the school medical work is very satisfactory on the whole, although not as effective as it was during the first year. At that time the parents believed treatment to be compulsory. Now they are aware that they need not have their children treated unless they wish to. This knowledge detracts from good results. In many instances it was found that while parents were willing to have their children treated, they were unable to give the time necessary for attendance at a dispensary for that purpose. At a written request of the parents a nurse accompanies the child to a dispensary.

Cooperation of Physicians and Dispensaries.—Private physicians and dispensaries lack cooperation and take little interest in the work, which is detrimental to efficiency, as the Department of Health considers a case closed when it receives notice from a physician that the child is under his treatment. The Department does not question the fact that a child is under medical care if a statement to this effect signed by a physician is presented. All the children presenting certificates of treatment are reexamined by the medical inspector, who notes on the child's record and forwards to the Department of Health a statement as to whether, in his opinion, such treatment is adequate. There is no law by which the Department of Health can enforce any further action. The Department has information that some physicians take advantage of this and carry on a trade in certificates sold at 10 cents apiece. A certain druggist is said to be using pads signed by a physician and selling them as certificates for school purposes. He is said to advertise these certificates at moving picture shows. Another physician in the Bronx had certificates printed and sold them at 25 cents apiece.

Out-patient departments of hospitals, dispensaries and clinics to cooperate very little in reporting the results of treatments, although they have been asked many times to do so and special blanks for reporting were distributed among them. The need of free dental clinics is very urgent, as there is a great lack of free dental facilities for the poor.

Cooperation of Principals and Teachers.—In exclusion cases the cooperation is perfect, the principals excluding children whenever they are referred for such purposes by either the inspector or the nurse.

In recommending children to the inspector or the nurse for special examination, cooperation depends largely upon the interest of the teacher or principal in the work. The teachers have so many other duties to attend to that they find little time to devote to inspection of children or to assisting the nurse. They do, however, recommend cases for special examination in instances where marked defects exist.

In helping in follow-up work and in application of corrective measures advised by the inspector the efficiency of cooperation reduces itself again to the personal equation with principals and teachers. All depends on the interest of the individual teacher and principal. In the four downtown schools which were visited the principals showed great interest in the work, and there was perfect cooperation with the work of the nurses.

Results Obtained by the Division of Child Hygiene.—The department reports that during 1911, according to their records, 86 per cent. of the children found to be suffering from defects other than bad teeth were placed under treatment. The following is the record of treatment: [1](58 per cent. of the cases were reported as under treatment by private physicians.)

Kind of Cases Treated	Number Treated by Private Physicians	Number Treated at Institutions or Dispensaries	Total
Medical	20,621	11,067	31,688
Surgical	11,835	10,431	22,266
Glasses	5,530	5,666	11,196
TOTAL	37,986	27,164	65,150

The number refusing treatment was reported as 6,431 and the number discharged from school as 5352.

II. *Responsibility of the Department of Education in the Matter of the Physical Condition of the Child.*—The Department of Education is at present responsible for three factors in the health condition of the school children; and these are: (1) The sanitary condition of schools; (2) Instruction in physical training, and (3) the segregation of backward and mentally defective children.

The first matter, the sanitary condition of schools, is under the control of three committees of the Board of Education: The Committee on Buildings, which has charge of the planning of the buildings, the placing of furniture, and determining the character of the ventilating plant; the Committee on the Care of Buildings, which has charge of the running of the plants and of the janitors; the Committee on Supplies, which has to do with the furnishing of all class room supplies.

The instruction in physical training and the care of backward and mentally defective children are under the City Superintendent of Schools. There is no concentration of all the activities of the Department of Education pertaining to health; there is no uniformity of policy, as the administration is scattered; and there is no localization of responsibility. Orders with regard to health matters travel from committee to committee, undergoing many changes on the way. The janitors, who are theoretically under the orders of the principals, form an independent body under a supervisor of janitors. Instead of being hired to keep the schools in good condition, the schools are farmed out to them on contract. They receive a lump sum of money for which they agree to keep the school in good condition. The results of this system are unsatisfactory. The advisability of changing the system is being considered by the Special Committee on Schools of the Board of Estimate and Apportionment.

Heating and ventilation in the schools of New York City are so poor as to be a matter of great concern. The subject has received much attention on the part of various civic organizations and some studies on heating and ventilation have been made.

There is no consensus of opinion as to the best system of ventilation, but experience has shown that there are serious defects in the artificial plants prevalent in the schools to-day, and many are advocating a return to the old-fashioned method of ventilating solely by open windows. It cannot be said, however, that the system of ventilation by artificial means has had a fair trial, because in most cases the plants have been under the management of janitors who are not fit for handling this kind of delicate machinery. In one or two instances, where the apparatus was intelligently used, the results were found to be satisfactory. But it is the opinion of those people who have had success with the ventilating plants that at present they must be expensive in order to yeild good results.

[1]Monthly Bulletin of the Department of Health for April, 1912 p. 103.

Mrs. S. S. Wise visited a number of schools for the Public Education Association and found that in most of them the ventilating systems were out of order, and in some of the rooms the temperature was from 75° to 80° F.

The committee has not inspected the sanitary conditions of the grammar schools, but it has made an investigation of the high schools, which may be taken as typical cases, because they are under the same management as the other public schools.

1. *Sanitary Conditions of the High Schools.*—(1) System of ventilation.—Only one school reports ventilation by doors and windows, three report direct and indirect ventilation, and the rest have the mechanical apparatus.

(2) Average dimensions of class rooms and average number of students per room.

Feet	Number of Pupils	School
25 x30	30	Richmond Hill
30 x35	35	Bushwick
20 x25x13½	32	Manual Training
26 x26	36	Stuyvesant
21 x25	38	Wadleigh
22 x25	35	Morris
21 x25	33	Erasmus
22 x28	38	Eastern District
28 x22	30-35	Commercial
26½x20½	..	DeWitt Clinton
25 x25	41	High School of Commerce

The size of classes in other schools varies so much that no average can be stated.

(3) Kind of desks used.—Six schools have adjustable desks, others use the non-adjustable kind.

(4) Windows.—There is an average of three windows to a classroom.

(5) Cleaning.—Most of the schools use damp or oiled sawdust for sweeping and cloths or feather dusters for dusting. In the majority of cases the floors and windows are washed once a month, in some only two or three times a year.

(6) Temperature and Humidity.—The average temperature of the classrooms is 68°. In none of the schools is there a test for humidity. In many the heating and ventilating systems are not working properly.

2. *Physical Training.*—No study was made by the committee with reference to the physical training of children in the grammar schools. Inquiries with regard to high school gymnasium equipment and attendance were made by the committee in connection with a study of medical inspection of high school students, and the following is a summary of the conditions found.

The gymnasium equipment in most schools is fairly adequate. Only one, the High School of Commerce, has a swimming pool.

The number of shower baths varies from 1 to 24, with an average of 10 to a school. Seven have none.

Only one school has special exercise rooms for physical defectives.

All the schools except one report that a number of talks on hygiene are given during the year by physical training, or biology teachers, or both. Students are required to pass examinations in hygiene in some of the schools, but not in all.

Gymnastics are generally required twice a week and attendance is compulsory. In all but one school there are periods after lunch. Most of the schools require gymnasium suits for girls but not for boys, the time being too short to allow for change.

The ratio of gymnasium instructors to pupils is, on the average, 1 to 500. At the Curtis High School there is one instructor to 986 students.

3. *Study and Provision for Backward and Defective Children.*—The worst cases of backwardness are selected by the principal and reported to the inspector on graded classes, a physician who visits in various schools and examines mentally and psychologically. If there are enough of these children found in one school, they are put into classes by themselves and a special teacher is engaged. These special teachers are under the direction of one superintendent.

There is a good deal about the system that is lacking. In the first place, the principal does not know "backwardness" in its various phases. Only the worst cases have been examined and segregated, while there are many border-line cases which get no special treatment or instruction. There should be more physicians engaged in this work—one cannot do it satisfactorily. At present the children receive no medical care.

Medical Inspection in High Schools.—With regard to medical inspection in high schools the following is a summary of the facts obtained, in answer to a questionnaire sent out to all the high schools of the city, some of which were visited in this connection by the Executive Secretary of the Committee.

1. *For contagious diseases.*—Of the eleven schools reporting medical inspection for contagious diseases, examinations are made by physicians, in five, and by teachers or nurses in the others. In a few instances inspections are made daily and in the others only in suspected cases. Most of the schools keep no records of the number of cases detected. One, however, reports from 25 to 50, and another 31 for last year. A number of schools send the suspected cases home, only two reporting that the Board of Health is notified. On the whole, responsibility is left with the class teachers, who are often indifferent and ignorant in this respect.

The daily list of contagious sick reported to the Board of Health is too long for the teachers to go over every morning, and as a rule little attention is paid to it.

2. *For vision and hearing.*—Five schools report that examinations take place either by a physician or physical training teachers once a year or once a term. All others report that no examinations are made. Only three of the schools reporting examinations keep records, and in them 710 cases were found defective last year. In all of the schools where examinations are made, the pupils are advised to consult a physician or, go to a dispensary. Only three schools require the students to bring from their parents an acknowledgment of the school notice as to their defects.

3. *For defects other than those of eye and ear.*—In seven schools no examinations are made. In two only are general examinations made by a physician. In others they are made by physical training teachers. In one school the examination applies to candidates for athletics only. In the twelve schools reporting examinations, some inspect the students once or twice a year, some once during the school course. One school reports that examinations are made for teeth; another (Wadleigh), where a physician is employed permanently, inspects for teeth, glands, nose, throat, heart, lungs, back, skin, nervous disorders, digestion, and nutrition. Other schools do not specify the kind of examinations made. No special rooms for examinations, outside of the offices of the physical training teachers, are provided. Records are kept in all but one school. Six schools notify the parents of the defects and advise them to have the children treated by physicians and dispensaries. Seven schools give corrective gymnastic exercises.

The number of remediable defective cases found last year was 764 out of a registration of 7,255.

Only two schools examine for tuberculosis, and three for parasitic skin diseases. Only one school (DeWitt Clinton) keeps a record of what is being done after the defects are pointed out to the students and their parents. This school reports 59 cases of flat foot, 59 cases of scoliosis, 8 cases of hernia, 27 of bad teeth, and 8 miscellaneous ailments rectified.

Need of Medical Inspection in Parochial and Other Free Schools.—There are more than 209 parochial and other free schools existing in this city, which are either entirely out of the pale of the Department of Health control, or the control is minimized, owing to the lack of funds for carrying on this work. The Catholic parochial schools alone have, according to the statement of the superintendent of the schools, made at one of the conferences on the health condition of children arranged by the committee, a registration of about 130,000. The schools do not have their own physicians, and the health control existing in them is very unsatisfactory.

Respectfully submitted,

E. H. Lewinski-Corwin,
Executive Secretary of the Public Health,
Hospital and Budget Committee of the
New York Academy of Medicine.

Appendix.

Department of Health, Division of Child Hygiene, Borough of Brooklyn.

Instructions to nurses.—The following methods will hereafter be used in treating children sent to the nurse by the Medical Inspector of schools:

Pediculosis.—Saturate head and hair with equal parts of kerosene and sweet oil, next day wash with solution of potassium carbonate (one teaspoonful to one quart of water), followed by soap and water.

Favus, Ringworm of Scalp.—Scrub with tincture of green soap, cover with flexible collodion. Severe cases: Scrub with tincture of green soap, paint with tincture of iodine and cover with flexible collodion.

Ringworm of Face and Body.—Wash with tincture of green soap, and cover with flexible collodion.

Scabies.—Scrub with tincture of green soap, apply sulphur ointment.

Impetigo.—Remove crusts with tincture of green soap; apply white precipitate ointment.

Molluscum Contagiosum.—Express contents, apply tincture of iodine on cotton tooth pick probe.

Conjunctivitis.—Irrigate with solution of boric acid.

SUMMARY.

The matters pertaining to the health and comfort of the school children are confided partly to the care of the city Health Department and partly to that of the Department of Education. The Health Department does this work through the Bureau of Child Hygiene; the Department of Education through a number of committees.

I. *The Department of Health.*

1. The work of the Child Hygiene Division is carried on by physicians and nurses.

(1) The duties of the physicians.—The physicians make physical examinations, diagnose suspected contagious disease cases excluded from school, make absentee and other home visits.

(2) The duties of the nurses.—The nurses exclude suspected contagious disease cases, make class inspections, and do follow up work in the homes.

2. The present system differs from the original plan in several particulars.

(1) The nurses exclude suspected cases daily, instead of the physicians who used to visit the assigned schools every morning for that purpose.

(2) The routine class inspections are made by the nurse once a month instead of by the physician once a term as formerly.

(3) The physician visits each school for two days in succession, at an average interval of about ten days, making physical examinations and visiting the excluded and absentee cases, while last year he devoted only the time that was left after the morning inspections to physical examinations in the school last visited.

3. Advantages of the present system.

(1) It has brought about some economy of money.

(2) It has markedly increased the total working hours of the staff by substituting nurses working 7 hours for physicians working 3 to 4 hours daily.

(3) It resulted in an increase of physical examinations made by inspectors almost double that of last year.

(4) The number of treatments for physical defects received by children has increased, due to the better supervision by the increased corps of nurses.

(5) The total number of home visits made by nurses has increased, although the average number of visits per nurse has decreased.

4. Disadvantages of the present system.

(1) The dissatisfaction on the part of some physicians, nurses and school principals with the innovation of having nurses exclude children for contagious diseases.

(2) The loss of school work occasioned by unnecessary exclusions due to faulty diagnosis.

(3) The duplication of work caused by the inspectors visiting excluded cases at their homes to confirm diagnoses.[1]

(4) The infrequent visits of the medical inspector to the school instead of former daily visits.

(5) The discontinuance of physicians' consultations with parents.

(6) The discontinuance of medical examinations for "working papers" at the school.[2]

(7) The overlooking of cases of tuberculosis by nurses in class inspections.

(8) The markedly decreased amount of time devoted to home visits by nurses.

(9) The diminished control of the contagious eye and skin diseases, especially trachoma.

5. The per cent. of New York school children needing treatment for physical defects is over 70, about 40 per cent. are found with defects other than teeth, and as large a number suffer from communicable eye and skin diseases.

6. The proportion of children to one nurse is 3,968, and to one school physician 8,124.

7. The physical examinations are not thorough. The children's clothing is not removed.

[1]This is not actually very great, as during the 5 months, Jan.-June, 1911, 16 cases were excluded daily from 150 schools in Manhattan, while in 1912 during the same period the daily average was 17 for 150 schools, or 1 case to every 4 or 5 inspectors.

[2]5 and 6 entail considerable loss in the efficiency of the system.

8. There is almost a total lack of free dental facilities for poor children.[3]

9. The cooperation of parents in following the advice of the physicians is fairly satisfactory.

10. There is very little cooperation on the part of medical practitioners and dispensaries.

11. The cooperation of teachers and principals varies greatly, according to the individual school. It is largely a matter of the personal interest of the teachers and principals.

12. The high schools have almost no medical inspection or supervision for their students.

13. The parochial and other free schools have no, or very little, medical supervision.

II. *The Department of Education.*

1. The control of the factors affecting the health of school children which are under the care of the Department of Education are scattered among a number of committees, so that there is no concentration of responsibility, which interferes with efficiency of administration.

2. The various matters pertaining to the health of the school child for which the Department of Education is responsible are as follows:

(1) The sanitary conditions of the school rooms, *i. e.* cleanliness, light, ventilation, and temperature.

(2) Proper janitor service.

(3) The detection of and provision for backward and defective children.

(4) Intelligent cooperation on the part of the teachers in the detection and correction of physical or mental defects.

(5) Physical training.

3. With the exception of physical training the control of these factors influencing the health of the child is at present unsatisfactory.

4. Physical training in the schools and the gymnasium equipment may be considered satisfactory.

RECOMMENDATIONS.

1. The present system of medical inspection in the schools by the Department of Health has not had a fair trial and should be continued for another year at least, before any definite judgment as to its efficacy can be safely reached. Meanwhile the possibility of an arrangement by which the physician, rather than the nurse, could see the suspected cases every day and also have frequent consultations with parents should be seriously considered.

2. In addition to their present work, the school inspectors should make a routine inspection of every class at the beginning of each term in order that the control of tuberculosis and some contagious eye and skin diseases may be stricter.

3. The average number of children per nurse and per inspector is too large at the present time. Efforts should be made to make the budget estimates on a basis of school population. In view of the prevalance of physical defects, the average proportion at the present time should be one nurse to every 2,500 children and one physician to every 7,500.

4. Physical examinations should be made more thorough and more frequent. The children, or at least the boys at first, should be stripped to the waist at physical examinations. The present plan of examining the child when it enters school, when it graduates and once in the interim should be changed. A child should be examined when it enters school and then every two years. The examination just before graduation does not have any particular importance.

5. In the nurses' work special emphasis should be laid on the follow up work. The burden of clerical work should be lightened. The unnecessary copying of the nurses' and physicians' record on the class card of the child should be eliminated.

6. The salaries of the nurses should be graded. Instead of their receiving, as a uniform wage, $900 a year, the initial wage should be $800, after a certain period of time increased to $900 and then again to $1,000. The gradation will act as a stimulus to efficient work.

7. Medical inspection should be instituted in the high schools which are entirely deprived of it at the present time.

8. The city should appropriate money for the enlargement of the force of the Child Hygiene Department so as to enable them to undertake the inspection of parochial and other free schools.

9. The medical practitioners and the dispensaries should be impressed with the importance of this work to the com-

[3]Dr. S. A. Knopf made an investigation of the dental facilities of the dispensaries of New York City for the Public Health Committee of the City Club. He found that over 16 dispensaries have dental departments with the average number of dentists in attendance 1-3. In only three dispensaries are special hours for school children arranged so as not to conflict with school hours.

munity and be urged to cooperate. Provision for dental clinics should be made, this being done if possible through the existing dispensaries.

10. In the Department of Education the responsibility for the conditions affecting the health of the school child should be concentrated. An improved organization should be worked out, which would bring under the jurisdiction of one committee the sanitary conditions in schools, the instruction of children in physical training and personal hygiene, the segregation and treatment of backward and mentally defective children, the instruction of teachers in matters of hygiene, mental defects and the commoner diseases in children, and cooperation with the Health Department which is a condition *sine qua non* for successful medical work in the schools.

It is suggested that this might be done by extending the scope of the present Division of Physical Training so as to include in it all of these activities, thus forming a special bureau of school hygiene.

11. There is an urgent need of a larger corps of physicians in order to extend the facilities for the examination and study of backward children.

12. An effort should be made to so modify the present system of employing and supervising janitors of school buildings that the principal of each school should have full authority over and responsibility for the work of the janitor.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Thirteenth Annual Meeting, Held at Montreal, Canada, May 31 and June 1, 1912.

(Special Report to the MEDICAL RECORD.)

DR. ALEXANDER D. BLACKADER IN THE CHAIR.

(*Concluded from page 226.*)

Sodium Nitrite in Arterial Hypertension.—Dr. WILLIAM H. PORTER of New York read this paper. After some preliminary remarks on the actions of medicinal agents in general and what they could and could not accomplish, he said that sodium nitrite should be classed among those remedies which acted indirectly, for it in no sense tended to remove directly the causes of hypertension in the vascular system. We knew exactly what could be accomplished with it, but the exact modus operandi by which it produced a dilatation of the over-tense vessels was not so clear. It was probable, however, that in the presence of water and HCl in the stomach, it was decomposed, and that its decomposition products, NO_2 and NO, were disengaged in the form of vapors which were irritants and strong oxidizers. These ultimately produced an impression upon the centripetal nerve-endings in the gastric mucosa, which impulse was carried to the vasomotor center and by the centrifugal nerves conveyed from the center of the vascular wall, thereby causing the expansion of the vessels. The slow decomposition of sodium nitrite, as compared with amyl nitrite and nitroglycerin, rendered it far more valuable when a continuous effect was desired; and its continuous action had been demonstrated both experimentally and clinically. Undue vascular contraction was very much more damaging than over-expansion, and from a purely nutritive point of view there was the greater necessity for modifying hypertension; for, without an ample and well-distributed nutritive supply, pathological conditions could not be removed or physiological ones reestablished. Sodium nitrite was, therefore, extremely valuable when employed before the vascular system had become too pathological to be easily influenced by its power to expand the unduly contracted arterioles. The dose should be from one grain up, at frequent intervals, until the arteries softened. Under its action, when properly given in suitable cases, the distressing symptom, dyspnea, nature's indication of tissue-starvation, was completely relieved, while oxidation reduction was greatly augmented, as evidenced by the changes for the better in the catabolic products found in the urine. Now, if at the same time, by other measures, the etiological factors were removed and the diet and digestion rendered perfect, the metabolic processes of the body could be, and often were, changed from an absolutely pathological state to one which was perfectly normal. It was the misuse of sodium nitrite, as, for instance, when the arterial system was contracted in connection with an enfeebled cardiac muscle, or when there was engorgement of the general venous system, that had caused many to doubt its efficacy. When, however, employed when and where it could assist nature, we had no more certain and reliable remedy in the whole materia medica.

DR. OSBORNE said that stimulation of the thyroid was indicated, but for this purpose large doses of thyroid were not required. Of the iodides, he preferred sodium iodide, as less irritating than the potassium salt. As to the nitrites, we did get a continuous action from them unless actual Bright's disease were present. Baking had not been mentioned, but he believed it to be one of the best measures at our command. There were times when it was not proper to lower the blood pressure, and therefore we could not make any fixed rule in this regard.

DR. GALLANT said there was one remedy which seemed to have been avoided, namely, water. He had found that sometimes great relief could be afforded by keeping the patient in bed for ten days at a time, without food, and giving him a gallon of water a day.

DR. CROFTON said it was a fact that very small doses of digitalis had the effect of reducing the blood-pressure in cases of intestinal intoxication. He had made a series of experiments in which large and small doses of digitalis were injected into rabbits, and as a result of these he was now accustomed to giving very small doses of digitalis, which he found had the action of the nitrites.

Saturday, June 1—Second Day.

The Proper Treatment of Diabetes Mellitus.—Dr. LOUIS KOLIPINSKI of Washington, D. C., said that the greatest fact in the treatment of diabetes was that it was curable by diet, though that it was curable by diet did not state the principle completely. Rather, it should be said that diet alone was the cure for the disease, and that by any other means this was an impossibility; moreover, that the use of any drug, organic extract, ferment, or enzyme was worthless, and therefore injurious. Gout, obesity, and diabetes were hereditary affections. Diabetes was caused, not by alcohol, but by over-eating to a degree of robustness in a laborer and over-fatness in the sedentary, and every diabetic had a previous habit of obesity or of excessive eating, with a fondness for special foods containing an excess of vegetable carbohydrates. The lesions of diabetes resulted from a permanent increase of glucose in the blood and its persistent discharge with the urine, and the essential cause of this was the destruction, more or less permanently, of the glycogen-making function of the liver. The subject of the disease was permanently bereft of the power of extracting sustenance from sugar and starch. He must henceforth abandon the proverbial staff of life, bread, or death would be the consequence. If, however, a diet were used which contained little or no carbohydrate, but on which he could live and thrive, no evidence of the continued existence of the disease could appear, no abnormal sensation or manifestation would be perceived, and he would live on in continued good health. The diet regularly prescribed by Dr. Kolipinski was as follows: *Breakfast.*—Artificial milk, eggs, ham or bacon, beefsteak, lamb, mutton, fish (fresh, salted, or smoked), raw tomato, a small cup of coffee or tea with cream. *Dinner.*—Artificial milk, clear broth, raw tomato and lettuce with mayonaise dressing, onion, cucumber, pickles; any kind of meat, fish, game, fowl, sausage, tongue, brain, sweetbread; any kind of cheese. *Supper.*—Artificial milk, fish eggs, cold meat, cheese, curds, a glass of cream, tea or coffee with cream. *At bed-time,* if desired.—Artificial milk or a glass of cream. The artificial milk was composed of raw egg, 2 teaspoonfuls of malt extract, and 4 teaspoonfuls of olive oil, which were beaten up together and to which was gradually added, while stirring, one pint of water. It was seasoned to the patient's taste with salt. In three or four months various vegetables and fruits might be allowed, if found not to produce glycosuria. Varied and repeated experience, he said, had proved that this dietary furnished food even more than enough for life, health and comfort. The only medicines used in the treatment were saline purgatives, given when the patient had constipation, hemorrhoids, or the fat habit. The diet mentioned, when partaken of for three or four days, invariably brought the specific gravity of the urine to normal or subnormal, and not a trace of glucose could be detected by the ordinary tests. The diabetes was cured as it were by crisis and the continuance of the cure depended upon the faithful observance of the regimen. Under this method the disappearance of glycosuria was absolute, irrespective of how recent or how old the case, how mild or severe the symptoms, or what the quantity of sugar in the urine. In essential diabetes of man glucose did not come from fat or proteid, whatever might be the case in experimental glycosuria. It was of great importance to guard a cured patient from his former habit of over-eating and obesity, and it might be necessary to reduce the daily

quantity of the artificial milk. The sparing use of alcohol and tobacco need not be prohibited. Having referred to various complications of diabetes, he said that beginning acidosis might vanish and the acids, fat derivatives, found in the urine in advanced cases might likewise be removed together with the sugar, but where evidences of the onset of diabetic coma presented themselves, the case was a lost one. In conclusion, he stated that in the cases treated by him, the previous duration of the malady had been from one month to twelve years, while the ages of the patients varied from young adult life to old age. The results obtained were precise and invariable when the dietary was faithfully adhered to, and it was with confidence that he reiterated the claim that by this method any diabetic free of terminal disease could be speedily and permanently cured.

Dr. Crofton said he was convinced that a person once a diabetic was always a diabetic. The sugar in the urine might be reduced by diet, but as soon as a carbohydrate diet was resumed it would return. In light cases it was easy to keep the sugar down, but more difficult in the severer ones, as the patient continued to manufacture sugar even if the diet were restricted to meats and fats. Diabetics should be allowed a certain amount of carbohydrate—say, 100 to 200 grams of white bread. To maintain a strict diet for an indefinite period was not only bad practice, but decidedly dangerous, even in mild cases. In the severer ones it was still more dangerous, and therefore we had to strike a balance in the matter. It was more important to keep the patient in good nutritional form than to have his urine free, or comparatively free, from sugar.

Modern Methods of Drug Standardization.—Dr. F. E. Stewart of Germantown, Pa., having stated that his object was to present to the Society a plan for teaching drug standardization which he had recently employed at the Philadelphia College of Pharmacy, reviewed, as a means of gaining an adequate idea of the subject of modern standardization, the standardization work of the U. S. Pharmacopœial Convention and its Committee of Revision during the past two decades. He then went on to say that drug standardization, in its large and comprehensive meaning, consisted in fixing a scientific nomenclature, in providing methods for insuring uniformity in composition, physiological action, and therapeutic effect; in adjusting finished products to fixed standards and keeping them up to the standard for a sufficient length of time to permit their proper application as therapeutic agents; in reducing this knowledge to law and embodying it in such system that we may have a science of materia medica; in embodying this knowledge in text books and teaching it to the medical and pharmaceutical professions, so that it may be used by physicians and pharmacists in their respective arts. Therefore, the importance of drug standardization could not be overrated. He next described chemical standardization, botanical standardization, pharmacological or physiological standardization, the bacterial-count method of standardization used in preparing bacterial vaccines, standardization by testing for the absence of contaminating bacteria, serological standardization, therapodynamic standardization, and clinical standardization. The object of therapodynamic standardization was to determine the activity of individual lots of the drug or preparation tested by observing and, if possible, measuring its effects upon diseased tissues, while that of clinical standardization was to determine the value of the drug as a therapeutic agent. Then followed the tabulated classification of the subject which he had of late been employing in his lectures. Methods for the determination of the identity, purity, and strength of medicinal chemicals, and standards for these, Dr. Stewart said, were well exemplified in the U. S. Pharmacopœia, and the extension of this work to the unofficial materia medica was rapidly being brought about by the American Medical and the American Pharmaceutical Associations. Pharmaceutical assaying might be defined as the art of determining the amounts of medicinally active constituents of drugs and their preparations. As such, it was an exceedingly important link in the chain of progress binding together medicine and pharmacy under the inclusive science of pharmacology. The possibility of deterioration was an important consideration for the therapeutist; but, fortunately, only a few drugs and their preparations were subject to rapid deterioration. Among these were digitalis, strophanthus, and ergot preparations. A considerable portion of the paper was devoted to the subjects of standardization of biological materia medica, including diphtheria and tetanus antitoxins, and botanical or pharmacognostic standardization. In speaking of pharmacodynamic standardization he took up the consideration of a number of individual substances, describing the blood-pressure method for the standardization of epinephrin and products of the suprarenal gland, and the physiological standardization of ergot, cannabis indica, cardiac stimulants, such as digitalis, strophanthus and apocynum, and cardiac depressants, such as aconite and veratrum.

A motion having been made that Dr. Stewart's paper be referred to the Council, with the request that they should bring it to the attention of the Revision Committee of the U. S. Pharmacopœia and of the American Pharmaceutical Association, an amendment was offered to the effect that the paper be referred to the Committee on Therapeutic Research, which should confer with Dr. Stewart as to the best steps to be taken to have it considered by the bodies named; and the motion, so amended, was carried.

The Value of Enterostomy in Ileus.—Dr. Lewis H. Taylor of Washington, D. C., read a paper in which the conclusions were as follows: (1) Enterostomy offers an excellent chance to a class of ileus cases formerly always fatal. (2) It should be done before complete bowel paralysis and before the abdominal muscles are stretched beyond their limit of tonicity. (3) The lower ileum should be the region of election for the operation. (4) The opening should not be made in the colon. (5) Old people, fat people, and people whose abdominal muscles are weakened from any cause offer an unfavorable prognosis. The paper was based on a series of twenty cases occurring in his practice during the past two years. The object in opening the bowel, he said, was to permit the escape of gas and fluid content, and upon the gut's ability to empty itself would depend the success or failure of the procedure. In ileus, or at least those cases of it where the condition was good enough to warrant enterostomy, peristalsis had either ceased or become so feeble as to be negligible, and we had to rely on the contractions of the diaphragm and of the parietal abdominal muscles. If either of the latter forces was much weakened we could not expect to get much result. Therefore to allow tympanites to go on to a high degree was to invite disaster. The ideal time for enterostomy was before peristalsis had ceased, but when it had become apparent that it was going to cease, in spite of the ordinary remedies; and the only reliable ways to determine this were by the frequent use of the stethoscope and careful observation of the character of the vomitus. The larger number of his cases had been operated on for the cause of the condition, and in such, a loop of bowel could be drawn out through the original incision after the sutures had been cut. Where the patient was nearly moribund sensation was so much obtunded that no anesthetic was required; when this was not the case he had given a light primary ether anesthesia. In reflex ileus where there had been no previous incision he had used local anesthesia. A patient needing enterostomy for ileus was in no condition to be moved. The operation should be done in the patient's room, and should, furthermore, be of the simplest and quickest character. It was his firm conviction that a slow, deliberate operation, with the usual operating room paraphernalia, technique, and courtesies, would kill every patient. Having described the technique of the procedure, he said it was extremely important to get the enterostomy low down in the ileum for two reasons: first, the further away it was from the pyloris, the larger the area of distended gut that would be drained; second, the nearer the pyloris, the more acid would be the character of the discharge which later would be thrown out over the skin and the greater the interference with nutrition when food could be recommended and the wound expected to heal. In appropriate cases, where the abdominal muscles were not stretched beyond their limit of tonicity and there was still some bowel power, the relief was immediate, and the quantities of gas and pea-soup bowel content discharged enormous. Cessation of vomiting took place almost at once, and as a rule did not recur. If it did, gastric lavage, to clean out the bowel content which had regurgitated before the enterostomy was done, would usually suffice to check it. The character of the pulse soon improved, and in a few hours there was a change in the patient from the appearance of imminent death to one of comparative comfort. In but two instances had he found it necessary to resort to operative interference to close the fistula. So far as his individual judgment went, he had no hesitation in saying that, in his opinion, everyone of his twenty-one patients would have died promptly if enterostomy had not been performed. Sixteen of the series were cases of peritonitis due to various causes, two were incident to toxemia outside the abdominal cavity, one followed on the third day after a high-forceps delivery and post-partum hemorrhage, and one was reflex. Of the two toxemic cases, in both of which the patients died, one was due to lobar pneumonia in a woman 8½ months

pregnant, and the other to a general gas bacillus infection in a woman operated on for a large, partially strangulated uterine fibroid. Excluding these two, the series showed a mortality of 16.6 per cent.

Note on the Treatment of the Gastric Neuroses.—Dr. Reynold Webb Wilcox, in this paper, said that formerly all the neuroses of the stomach, generally enumerated as twelve, were grouped together under the title "nervous dyspepsia," and from the therapeutic standpoint perhaps this was not so illogical as might be supposed. Accuracy in diagnosis was by no means to be deprecated, but in the careful cultivation of the narrower field the greater general condition was not to be lost sight of. From the standpoint of the therapeutist even the substitution of the term gastric neurosis for nervous dyspepsia had not been altogether fortunate, for it had favored the conception of a gastric neurosis as a morbid entity. The conclusion was tenable that the chemistry of gastric secretion and the physics of stomach motility were not elucidated in textbooks built on an isolated laboratory investigation. This should be predicated upon what the organism might do when its pathology was physiology gone wrong and a neurotic subject was doing his or generally her, utmost in the way of vagaries. In general to the treatment given under the several divisions of the subject, as presented in the standard books, but little exception could be taken. Criticism, however, needed to limit what seemed to be the extensive and improper use of sodium bicarbonate in the treatment of hyperchlorhydria. Reflection and a more careful study of the chemistry of gastric secretion should lead to the substitution for this of magnesium oxide if one looked toward permanent benefit. As there was no panacea for the neurotic condition dominating the individual, so there was no specific for any one of the twelve varieties of gastric neuroses. Each individual should be studied as an entire organism. With many neurotic women in the higher walks of life, in addition to the regulation of habits of life and the employment of various physical agencies, much benefit often came from the administration after meals of ten drops of tincture of nux vomica, six grains of resorcinal and a drachm of peppermint water diluted in two ounces of water. This paper, Dr. Wilcox said, was a plea, not for the less consideration of morbid gastric processes, but for better and more attention to the individual who unfortunately possessed an unruly stomach.

Other papers read were: "The Treatment of Somatic Death" by Dr. W. Wayne Babcock of Philadelphia; "The Therapeutics of Sacroiliac Relaxation," by Dr. A. Ernest Gallant of New York; "Medical Treatment of Gastric and Duodenal Ulcer," by Dr. L. M. Gompertz of New Haven; "Filariasis; with Report of a Case Treated with Dioxydiamidoarsenobenzol," by Dr. Noble P. Barnes; "Dioxydiamidoarsenobenzol in the Treatment of Various Clinical Forms of Syphilis," by Dr. J. M. Anders of Philadelphia.

Election of Officers.—The officers elected were as follows: *President*, Dr. Noble P. Barnes, Washington; *First Vice-President*, Dr. Howard VanRensselaer, Albany; *Second Vice-President*, Dr. Robert T. Morris, New York; *Third Vice-President*, Dr. Francis Marion Pottenger, Los Angeles; *Secretary*, Dr. Lewis H. Taylor, Washington; *Treasurer*, Dr. A. Ernest Gallant, New York; *Chairman of the Council*, Dr. Reynold Webb Wilcox, New York; *Members of the Council*, Drs. James C. Wilson, Philadelphia, Alexander D. Blackader, Montreal, and J. Madison Taylor, Philadelphia; *Committee on Admissions*, Drs. Frederic H. Gerrish, Portland; R. D. Rudolf, Toronto, and Philip King Brown, San Francisco; *Committee on Competitive Therapeutic Research*, Drs. Wilcox, Thomas E. Satterthwaite, New York, and Spencer L. Dawes, Albany; *Editor of Transactions*, P. Brynberg Porter, New York. The next annual meeting will be held in Washington, D. C., in May, 1913.

The Heart Sounds of Sick and Healthy Children.—W. Schlieps states that in older children suffering from severe forms of infectious disease the first sound of the heart becomes inaudible. The relaxed condition of the skeletal musculature suggests a similar condition of the heart muscle. The softening of one heart sound at the same time that the blood pressure remains normal indicates that it is the first sound that is muffled. The remaining audible tone is louder over the pulmonic area than at the apex. The administration of camphor causes both tones to become more distinct, even in cases with a normal blood pressure.—*Monatsschrift für Kinderheilkunde.*

Medicolegal Notes.

Itinerant Physicians' License—Discriminatory Exemption Renders Statute Invalid.—In an appeal from a conviction of practising medicine within the State of South Dakota as an itinerant physician without first having obtained a license from the board of medical examiners, the constitutionality of Section 22 of South Dakota Laws 1903, c. 176, was raised. The act provides that any physician attempting to practise as an itinerant physician shall, in addition to the ordinary physician's license required under the act, procure an itinerant's license from the State Board of Medical Examiners, for which he is required to pay the sum of $500 per annum. Section 22 of the act provides that it shall not apply to resident physicians and surgeons of the State regularly licensed and practising in the State at the time of taking effect of the act.

Those portions of the act regulating the practice of medicine, prescribing the qualifications therefor, and appointing a medical board of examiners are within the police power of the State; and the provision permitting those practising within the State at the passing of the act to continue without other evidence of competency is not invalid as being discriminatory.

The provision of the act, however, providing for an itinerant's license and the payment of a fee therefor, is not, and does not pretend to be, legislation involving the exercise of police power. It contains nothing requiring fitness or qualifications. It is an occupation tax, involving only the exercise of the taxing power. But by Section 22 of the act all physicians licensed to practise in and residents of the State at the time of taking effect of the act, as well as certain other persons named, are exempted from payment of the itinerant license, or occupation tax. The statute, being an exercise of the taxing power, is subject to the constitutional provision requiring that "all taxation shall be equal and uniform."

The Legislature may lay an occupation tax on physicians and surgeons as upon other professions and occupations. The classification of medical practitioners into two classes, those who practise as itinerant physicians and those who do not, is not unreasonable, and the imposition of a tax on itinerant physicians is not in conflict with the constitutional provision.

But Section 22 of the act attempts to exempt all resident physicians and surgeons licensed and practising in the State when the act took effect from payment of the tax. Viewed as an attempt to exempt a portion of a class conducting a professional practice as itinerant physicians in identically the same manner, the provision is unconstitutional. Its practical effect would be that every physician residing in and licensed to practise in the State prior to the date of the act may practise as an itinerant, free from the tax, while every person who, even though a resident of the State where the act passed may have been licensed as a physician after that date, as well as every physician whether licensed or not, who became a resident of the State after that date, would be subject to the tax.

If, however, the section is regarded as an attempted classification of itinerant practitioners, the classification rests solely upon the fact of residence and practice in the State prior to a certain date when the act became operative. Such a statute discriminates against citizens of other States, and is in violation of Article 14 of the Federal Constitution. Residence within or residence outside of a State cannot be made the basis of discrimination in taxation of persons engaged in the same occupation or profession.

The invalidity of Section 22 rendered the act void so far as it relates to itinerant physicians; but the remaining portions of the act relating to examination and matters incident thereto remain valid.—State v. Doran, South Dakota Supreme Court, 134 N. W. 53.

Privileged Communication Statute Applied to Result of Autopsy.—In an action against a municipality for injuries alleged to have caused the death of the plaintiff's wife by reason of a defective highway, the physician who had attended her, and who, without the plaintiff's permission and against his protest, had performed an autopsy to ascertain the exact cause of death, was offered as a witness for the defendant. The plaintiff contended that as neither the deceased nor the representative of her estate had waived the statutory privilege it was error to allow the physician to testify as to the results of the autopsy and his conclusions therefrom as to the cause of her death.

This question does not seem to have been decided before. The court held that the evidence was erroneously admitted.—Thomas v. Byron Tp., Michigan Supreme Court, 134 N. W. 1021.

FALSE GIGANTISM, COMPLICATED BY TRAUMATIC OSTOSES.

By WALTER WILSON GRIFFIN, M.D.,

NEW YORK.

SURGEON TO THE FRENCH HOSPITAL, ST. MARK'S HOSPITAL, AND BELLEVUE DISPENSARIES.

THE clinical features of the following case have seemed to me to be of sufficient interest to justify publication. The history of the case is as follows:

S. G., a boy of eleven, of Russian Jewish parentage, born in the United States, came under my care on September, 1911, in the Surgical Clinic of the University and Bellevue Hospital Medical College. Family history yielded no facts of clinical interest; furthermore, a physical examination of both parents was made and they were found healthy.

Personal History.—The third of four children; a full term child; labor was normal. He sleeps and eats well, bowels regular, urination normal, weight at a standstill. He had gastroenteritis when six weeks old of two weeks' duration; measles at three years. Except for these periods of illness the boy has been well. A careful questioning of both the patient and his parents failed to furnish any venereal history.

Present illness began six weeks previous to the time of his first visit, when he fell from a wagon, striking his right shin. A localized painful swelling of the leg was immediately noticed. The pain from the trauma subsided within a few days, but the swelling persisted and has gradually increased to the time of his first visit, September 16, 1911. There was at no time any fever or disability. Since the injury the parents have observed that the injured leg is longer than the other. Of late they have also noticed the presence of two hard, painless immovable masses upon the bone. Even now, except for an uneven gait due to the unequal length of the legs, there is no other cause for complaint. There is absolutely no pain, the boy sleeps and eats well, and can sustain his weight on the longer leg as well as upon the shorter without any discomfort. The right foot is likewise larger than the left, since the boy requires a shoe two sizes larger on that side than on the other.

Physical Examination.—A spare, somewhat sallow boy, fairly well developed for his age, and in good general condition. His face appears small according to the normal ratio between face and cranium; the left eye is smaller than the right and placed one-quarter of an inch lower than it. The tongue is patchy, presenting smooth atrophic areas which are situated anteriorly. The skin presents several small fibroneuromata; similar ones are also seen in his male parent. The glands in the groin are palpable but not tender.

Examination of the thorax, abdomen, rectum, and genitals reveals nothing abnormal.

Bony Skelcton.—The frontal bones are unusually prominent. The upper extremities are equal both in length and circumference. The thorax and spine are normal. The lower extremities reveal an inequality in length below the knee, the femora being equal.

Measurements.—The right leg from the knee to the ankle is 1¼ inch (3.39 cm.) longer than the left. The right foot is longer than the left, and

Fig. 1.—The left leg supported by a ledger 1¼ inches thick brings the anterior superior spines and patellæ on a level. The general swelling of the leg and the distinct tumor formation are well shown.

also broader, though this is less apparent. Attached to the right tibia are two smooth, dense, hard, painless masses, apparently consisting of bone, the larger one situated 6 inches (15.54 cm.) from the tuberosity of the tibia, and measuring 2 inches long and 1¼ inch broad (5.18 cm., 3.39 cm.), the smaller tumor situated 9 inches (23.31 cm.) from the tuberosity and measuring 1⅛ inch by ⅞ inch (2.93 cm., 2.28 cm.).

X-Ray Plates.—The *x*-ray plates show the local swellings of the right leg due to two subperiosteal bony masses and also to a certain amount of thick-

ening of the soft parts. In contradistinction to the two masses seen attached to the surface of the tibia there is a diffuse subperiosteal thickening of the fibula not apparent in its fellow of the opposite

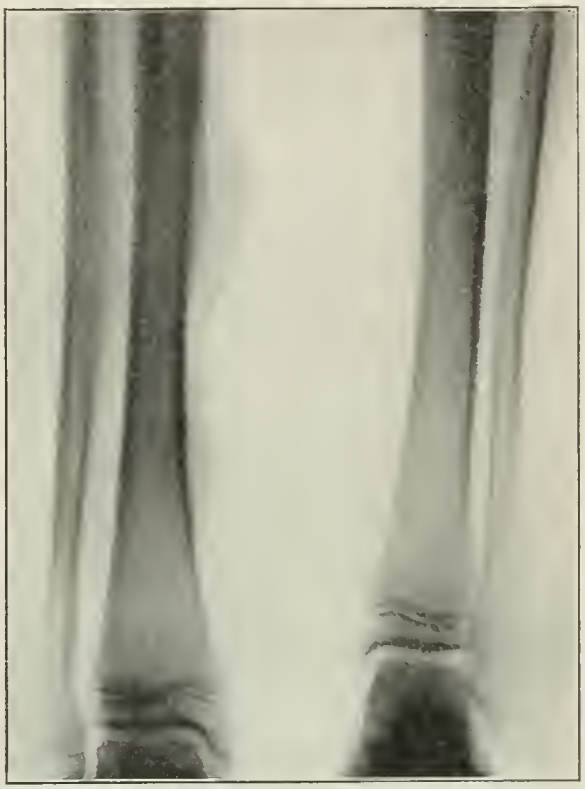

Fig. 2—An *x*-ray picture of both legs, showing tumor of the right leg, lengthening of the right tibia and fibula, and the parallel lines in the lower third near epiphyses.

side. The difference in length of the legs, 1¼ inch (3.39 cm.) is confirmed by the *x*-ray.

In *x*-ray pictures of young individuals lines parallel to the epiphyseal lines occur; they are symmetrically placed under normal conditions. In the case under consideration they are wider apart in the right (affected) tibia than in the left. This probably indicates that the increased growth of the right leg (lengthening of the bones) has not been merely since the trauma, but that it has existed since very early life.

X-ray plates of the feet show that the right astragalus and os calcis are distinctly larger in all dimensions than their mates on the opposite side, and that, all in all, the entire skeleton of the right foot is slightly larger than the left.

The interesting points of this case are best understood by examination of the appended photographs and *x*-ray pictures: The tumor mass consists of two sections attached to the bone, and these two subperiosteal bony masses do not encroach upon the shaft or marrow canal, so that their presence apparently does not account for the lengthening.

Other clinical data in reference to the case are: The blood count, which showed a slight anemia, but no foreign cellular content, and no relative percentage change from the normal. One Noguchi and three Wassermann reactions were independently made by three observers, and all were reported negative. In spite of this, a therapeutic test was now made, 0.02 gms., Ehrlich's 606 being injected, with no resultant change in the physical signs after two weeks.

A section of the tumor for microscopical examination was then removed. The Pathologist, Dr. Doughlas Symmers, reported as follows: "Microscopical examination of the bone reveals the presence of some sclerosis of the cancellous spaces. Microscopical examination of the soft tissues removed from the immediate vicinity of the bone reveals a quantity of poorly nourished fibrous tissue in which there are a number of empty vascular spaces, apparently of lymphatic nature. There is nothing in the histology to indicate the presence of syphilis or of a new growth."

The two diagnostic possibilities considered up to this time had been syphilis or new growth (sarcoma). Another explanation was now sought.

It is known that local overgrowth in the limbs occurs—sometimes an hypertrophy of all the tissues takes place. This is true gigantism. Again the hypertrophy may affect but one form of tissue, such as the adipose tissue, blood vessels, lymphatics or the bone—false gigantism. Such overgrowth, involving one or more toes, or fingers, or the foot, or hand, is of much more frequent occurrence than the more extensive types reaching to the knee or hip (elbow or shoulder).

It seemed reasonable to conclude that this is a case where the hypertrophy involves the bones more than the soft parts, a condition constituting the aforesaid false gigantism. I might add here that *x*-ray plates of the skull show no enlargement of the pituitary fossa. Further, it seems that the two bony tumors of the tibia represent subperiosteal effusions of blood which had become organized into bony tissue—traumatic ostoses.

This case is therefore an hypertrophy mainly of the bony skeleton of the right lower limb below the knee, complicated by two traumatic ostoses.

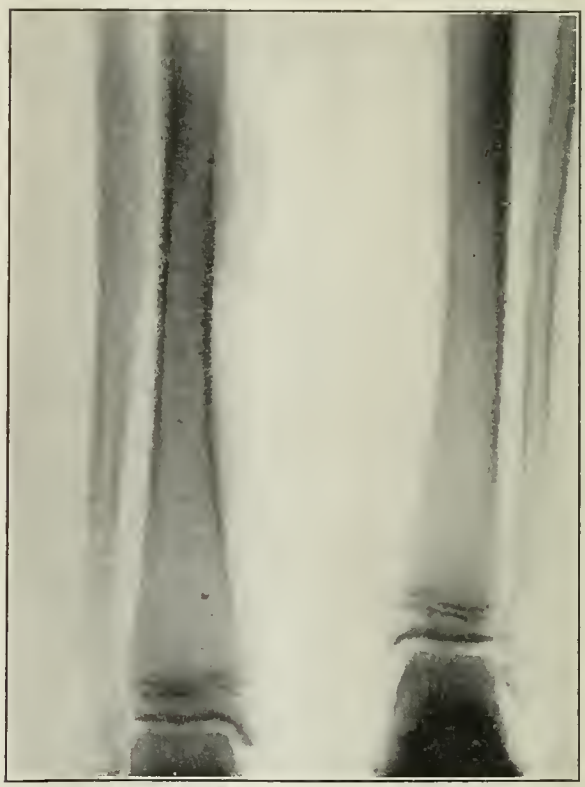

Fig. 3—An *x*-ray picture of both legs taken at a different angle from Fig. 2, but showing the same features.

I wish to thank Dr. J. C. A. Gerster for permission to report this case and for valuable assistance; also Dr. Lewald of the Edward Gibb's *x*-ray laboratories, for his admirable *x*-ray plates.

64 West Fifty-sixth Street.

RESEARCH WORK IN LIFE INSURANCE MEDICINE.*

By FREDERICK L. HOFFMAN, Ph.D.

NEWARK, N. J.

STATISTICIAN, PRUDENTIAL INSURANCE COMPANY OF AMERICA.

The scope of life insurance medicine is constantly broadening and the general and specific functions of the medical director and the medical examiner were never of as much practical importance to life insurance companies and life insurance applicants as they are at the present time. The business of life insurance has so enormously increased during recent years that insurance protection has practically become a universal thrift function indispensable to the social wellbeing of the vast majority of the people. The average amounts insured for are much larger today than in former years and in a fair proportion of individual cases these amounts assume the size of a considerable fortune. Since the primary object of life insurance medicine is to safeguard the interests of the company and its policyholders against adverse selection, it is obvious that the duties of the medical director and the medical examiner are among the most responsible in life insurance administration and that they are essential to the attainment of the best possible financial results.† Life insurance medicine is, therefore, a separate and well-defined branch of general medicine, but its sphere is all-inclusive of the innumerable factors and circumstances which condition the duration of life in the individual and the mass of mankind.

The *fundamentals* of life insurance medicine are quite clearly defined and generally understood. The textbooks on the subject and the manuals of instruction are, broadly speaking, adequate to the purpose of protecting the interests of life insurance companies against the ever-present menace of adverse selection. Granting this much, and especially with regard to the elements of physical diagnosis, the evidence is quite conclusive that life insurance medicine has not made the brilliant progress attained in so many other and equally highly specialized branches of medicine. That this has not been the case is primarily to be attributed to the neglect of individual and collective research work, of which we witness the first beginning in the medico-actuarial investigation, the results of which will become available in the near future. To the truth-seeking mind, it has properly been said, "there are no obligations except the incontrovertible evidence." In the practice of life insurance medicine, perhaps as much as in the practice of medicine in general, much is still being taken for granted upon the basis of more or less questionable authority, some of which dates back to remote antiquity. Modern methods of science discountenance the acceptance of principles and beliefs which are not sustained by incontrovertible evidence warranting approximately identical conclusions, irrespective of circumstances or time. It is not my intention to make a special plea for the utility of the statistical method in medicine. It is quite possible to be led astray by conclusions derived from a large number of observations not subjected to a qualified and critical analysis, but in the light of past experience the assertion is warranted that this method has obvious advantages over any other yet devised as regards the determination of the factors of human mortality. It is, no doubt, true that the statistical method is often unsuitable for purposes and matters of medical detail, but the present discussion has reference only to the predominating factors of human mortality, which can be determined by means of the statistical method and most accurately and conclusively by that method alone.

Life insurance medicine may broadly be divided into seven sections—(1) the function and duties of the medical director; (2) the function and duties of the medical examiner; (3) medico-actuarial problems; (4) medico-statistical problems; (5) medico-legal problems; (6) medico-sociological problems; (7) insurance medicine in its relation to public health. The fundamental principles which underlie all of these is *the law of human mortality* and the factors which condition its duration from the hour of birth to the highest attainable age. There is no agreement, even among the most generally accepted authorities, as to what constitutes a precise definition of life, death, and disease. Even the term "law of mortality" has never been defined with scientific precision, as this is essential in the case of scientific laws which admit of no variation in point of space or time.* In the words of Corbaux, who was probably the most learned and philosophical writer on the subject, "Permanence is not an attribute of the law of mortality." I am not prepared to accept this conclusion, which, of course, depends largely upon the exact definition of the term. Most of the writers on the law of mortality have in mind the rate of mortality, which, of course, is subject to wide variations in space and time, in that it is fundamentally conditioned by innumerable circumstances which tend to lengthen or shorten the duration of life. When Süssmilch first laid down his principles of the order of God in the duration of life, he also was influenced chiefly by the observed regularity in the declinate of life from birth to the highest attainable age. Curves drawn on the basis of death rates, even for quite different classes of people or for different periods of time, conform in their broad outline quite closely to each other. The true law of mortality, as deduced from these curves, may be expressed in the statement that among equal numbers living the proportion dying will be greatest at birth, diminish rapidly to a minimum at about age 12, increase slowly to about age 50, and very rapidly thereafter to the highest attainable age. This law has all the elements of permanency, for it has not been found to vary essentially in any one of the numerous investigations which have been made by different methods to determine the rate of mortality or the average age at death, or the expectation of life, or other measures of life's intensity with a due regard to age and sex.

The work of Corbaux is practically unknown to modern readers, for, unfortunately, a contribution of the highest scientific character was printed in an edition of only 250 copies. In the discussion by Corbaux there are most useful observations on life's absolute intensity, on life's specific intensity, at each exclusively considered year of age, of the eight periods which naturally divide the course of human life, and finally, on the law of mortality developed under its modifications as conceived by the author and explained at considerable length. A reprint of this work would make a most useful contribution to

insurance knowledge and a study of this author cannot but broaden the conception of life insurance as it is related to medicine, biology, and even philosophy. It is true, however, that speculations of this kind throw no light upon the profound problem of age, growth, and death, which has been so admirably presented by Minot in his lectures at the Lowell Institute in 1907. It is a sad commentary on the neglect of the scientific study of normal and abnormal man, that while the rate of growth or physical development is known and understood with scientific accuracy for rabbits and guinea pigs, it is practically as yet a mere matter of scientific conjecture with regard to civilized man. The positive dearth of accurate data was never more precisely illustrated than in the paucity of facts confronting the Parliamentary Committee on National Deterioration, which desired to ascertain whether there had been a positive decline in the physique of the people of the United Kingdom. The *anthropometric data* contained in the archives of life insurance companies, if subjected to a qualified statistical analysis, would yield a veritable treasure store of useful and conclusive information. The best work of its kind in the field of American anthropometry is the classical report by Gould on the Physique of the American Soldier, prepared under almost inconceivable difficulties soon after the close of the Civil War. The investigation by Gould had its inherent limitations on account of the peculiar age distribution of men engaged in active military service and the conclusions, therefore, do not apply to the whole of the adult population, with regard to which it is so essential that the fundamental laws of growth and physical proportion should be better understood.

What is true as regards our ignorance of the true laws regarding the growth and physical proportions of civilized man, is equally true as regards the rate of human mortality as conditioned by the innumerable factors and circumstances which more or less determine the duration of the individual life and of life in the mass. The philosophical essay by Karl Pearson on *the Chances of Death* is one of the most illuminating contributions to the theory of applied statistics and the practical utility of the theory of probability. Having in mind the suggestion of Prof. Lexis that death in old age only is normal death, Pearson investigated the details of human mortality and he came to the conclusion that, regardless of the many diseases and accidents from which men die, these could be substantially classed into five great groups centering around five distinct ages in life. His mathematical researches lead him to the further conclusion that the curve of mortality should be made to include the waste of pre-natal life and by utilizing such data as could be had concerning deaths during the different periods of uterine gestation, he constructed a curve which practically conformed to the theoretical conceptions derived from the law of pure chance.

Karl Pearson is largely responsible for improved methods of statistical research. No writer has emphasized more emphatically the proper methods of science which should underlie research work in every field of human inquiry.* His definition of life and its origin and perpetuity are a most valuable introduction to the student of insurance medicine in its broader aspects. His observations on the *selective and non-selective death rate* are probably preliminary to more extensive investigations, which would seem to be required to precisely determine the truth of a most important assertion. In his discussion of the inheritance of the duration of life, Pearson states that the non-selective death rate or that portion which is conditioned by man's environment, is about 20 per cent., while the selective death rate or that portion which is conditioned by heredity, is about 80 per cent. of the total death rate. It is not shown upon what numerical basis these conclusions were arrived at, but there are few more important problems in insurance medicine than the exact ascertainment, if possible, of the probable inheritance of the duration of life.

The value of *family history* in life insurance medicine would not appear to hold the important position assigned to it in the earlier years of life insurance development. If the conclusion of Pearson is correct that the selective death rate accounts for 80 per cent. of the total mortality, then the family history of the applicant attains to very considerable practical proportions. In the absence of trustworthy registers containing the required proofs of the ages and causes of death of persons of former generations, it is obviously most difficult, if not impossible, to secure trustworthy answers to the questions relating to ancestry in the application blank. But, in a general way, however, these questions, at least with regard to life and death in general, are correct, as shown by insurance experience, according to which in the case of every 100 male applicants 37.4 per cent. of the fathers were living and in the case of female applicants 37 per cent. As regards mothers, it was shown that for male applicants 48.9 per cent. were living and for female applicants 47.6 per cent. These results are, of course, influenced by the age distribution of applicants, but it is quite clear that, in a general way, the essential facts of parental life and death at least are probably accurately returned. The subject becomes much more complicated as regards the causes of parental death, which there are strong reasons for believing are often deliberately misstated and particularly in the case of the most important causes, such as tuberculosis, cancer, insanity, suicide, etc. Research work in this direction would unquestionably disclose valuable facts which could be applied to the development of a more satisfactory theory of risk selection, for it has been shown by the investigations of Marsh, in behalf of the Mutual Life, that a family history of consumption is of serious significance as disclosed by the subsequent mortality experience. And much the same conclusions have been established by Hesse on the basis of the experience of the Life Insurance Company of Bale, who, in a report published in 1899, presents a most interesting analysis of the causes of death in the family history of insurance applicants.

In forecasting the probable longevity of the individual, it is necessary to take into account the *factors of safety* in the human economy, which have been so admirably described by Dr. Meltzer of New York City. It would be most useful to have these factors more precisely defined, for some of the conclusions of Meltzer and others on this subject may be questioned. Is it true, for illustration, that "every medical man knows that one kidney can be removed with entire impunity if the other kidney is normal?" As far as I am aware, no trustworthy data are available to show that the normal expectation of life of persons who have undergone this operation is not substantially curtailed. Is it true, as it is so often alleged, that the removal of the appendix is not, in at least a considerable proportion

*See Pearson's "Grammar of Science" and "Chances of Death and Other Essays."

of the cases, followed by a decrease in the average longevity? I am not aware that the conclusions advanced with regard to the non-injurious after-effects of the removal of the appendix are sustained by an adequate basis of statistical data subjected to a critical analysis by those qualified to do so. In fact, the whole subject of the after-effects of surgical operations and their relation to longevity has never been investigated with the required impartial medical and statistical skill. It would be difficult to conceive of a more complex problem confronting the seeker after truth. Considering the vast amount of hospital experience, it is lamentable that the subsequent results, like nearly all records of disease, should be so generally wasted. I am aware, of course, that some of these questions have been taken into account in the Specialized Mortality Experience, prepared under the direction of the American Actuarial Society, but the point may be raised whether the results are really useful for general purposes, since the number of cases considered was small and representative of a selected class. It must be self-evident that if any class of impaired risks is most carefully selected, the subsequent mortality must be considerably less than would be the case with a similar class of persons in the general population. The conclusion derived from the Specialized Mortality Experience that, contrary to expectation, those who have had otorrhea appear to be good risks, would hardly be accepted by the general practitioner, and certainly not by the specialist on diseases of the ear. The most serious shortcoming of the Specialized Mortality Experience is the absence of medical information, and particularly as to the causes of death. It is to be hoped that the forthcoming investigation by the Medico-Actuarial Committee will present in full the actual number of deaths and their causes for every specialized group considered. It would also add much to the practical utility of the investigation if the observations and comments were made with less brevity and with some attention to medical matters of detail, which, according to circumstances, may assume considerable importance. It may further be suggested that it would seem better to limit the groups to specific and well-defined medical terms, than to combine more or less similar but, according to circumstances, widely different diseases or abnormal bodily conditions. For illustration, the combination of inflammation, peritonitis and appendicitis, invalidates all conclusions with respect to any one of these three well-defined but quite dissimilar affections. The same is true of the combined group of renal colic, calculus, or gravel.

It is a distinctly hopeful sign that the requirement of the *blood pressure* test in the practice of medicine and life insurance is becoming more general, at least in the examination of applicants for large amounts. The classical treatise by Janeway constitutes a thoroughly scientific foundation for a more comprehensive future inquiry into the whole subject of blood pressure in its relation to life insurance medicine. The discussions by Cook, of Minneapolis, and Lankford, of San Antonio, on "Blood Pressure in Life Insurance," are indications of the direction which investigations of this kind are bound to take. Jackson, of Boston, in 1911, published some very interesting remarks on high blood pressure and arteriosclerosis, but the most scientific work of recent years are the admirable clinical observations on blood pressure, by Cook and Briggs of Johns Hopkins Hospital. According to Lankford, many thousands of tests have been made of healthy people of all ages and the systolic pressure has been found to range from 110 to 120 for young adult females and from 115 to 125 for young adult males. For older ages the range was from 145 to 160. For life insurance purposes, a much more precise statement, however, is required, and it would be desirable to have a sufficient number of tests made for, say, every ten years of life, commencing with age 20 and ending with age 70. The more exact requirements would also necessitate similar tables for the variation in blood pressure in disease in conformity to the methods adopted by Cook and Briggs.

The significance of a normal *pulse rate* is conceded by every one familiar with the elementary principles of medicine. The elaborate treatise by Mackenzie on the Study of the Pulse, would seem to constitute a complete guide to the use of this factor in physical diagnosis, as an indication of abnormal conditions of the heart and circulation. Tigerstedt's table showing the maximum and minimum frequencies of the pulse from ages 15 and upwards, is based on a comparatively small number of cases, which would certainly seem to make this table more or less unsuitable for life insurance purposes.* A minimum pulse at age 21 of 41 and a maximum of 96, may or may not be evidence of abnormality in the body, but when such figures are based on only 54 such cases the question may properly be raised as to whether the conclusions should apply to a business involving such large financial considerations as insurance. A more extended consideration of the subject by Gould in his report on the Anthropometric Statistics of the Civil War, also fails to meet modern requirements, in that most of the observations relate to men of comparatively young ages. It would seem, therefore, that the whole question should be made a subject of original inquiry, with a due regard to age and sex, and possibly to race and occupation.

While much has been written upon the effect of *alcohol* on the human body and the relation of drink to longevity, it is only within very recent years that really scientific contributions have been made to this important subject. The earlier work by Norman Kerr quite clearly established the incidence of alcoholism as a factor in the mortality experience of life insurance companies, and this has been fully confirmed by the mortality of the United Kingdom Temperance and General Provident Institution. In general terms it has been said "that the feature of the abstainers' mortality is a great saving after early manhood throughout all the working years of life; which saving increases up to middle age, and gradually rises to the normal rate of healthy life as old age is reached at, say, ages 70 or 75."

The scientific evidence of the effect of *alcohol* as a beverage has been most ably assembled by Sir Victor Horsley in his treatise on "Alcohol and the Human Body." The value of this work to life insurance companies cannot easily be overrated, more so in view of the statistical evidence disclosed by the analysis of the experience of insurance institutions differentiating abstainers from non-abstainers, with a considerable saving in premium charges to the former. Such work as has been done by Karl Pearson and others to determine the influence of parental alcoholism on the physique and ability of the offspring, is indirectly of value to life insurance com-

*See also table of pulse rates as given in Minot's "The Problem of Age, Growth, and Death," p 15.

panies as disclosing a method of research, which on the basis of large numbers may establish a correction at present entirely unknown. The thoroughly representative character of the Twelfth International Congress on Alcoholism indicates the direction in which the experience of life insurance institutions may prove of value to the cause of temperance and the general progress in public health. The lines of future research are made evident by recent contributions to the study of the "Influence of Alcoholism on the Degeneration of the Offspring" by Laitinen, the "Relation of Alcoholism and Tuberculosis" by Henschen, the "Action of Alcohol on Muscular and Mental Development" by Rivers and Webber, etc., etc. As a suggestive indication of the modern trend toward practical methods of influencing public opinion on the drink question, reference may be made to a "Manual on Alcoholism in Industry," published by the American Museum of Safety of the City of New York. The subject confronts life insurance companies not only with regard to the habits of non-abstaining applicants in general, but also in the case of applicants engaged in the manufacture and sale of intoxicating drink. The practice of companies with regard to these questions is quite varied, largely because of the absence of conclusive data. Every analysis of the mortality of persons employed in the manufacture and sale of alcoholic beverages, however, sustains the conclusion that the death rate in general is excessive and that in particular the mortality from tuberculosis, respiratory diseases, and liver diseases is considerably above the average. Research work along these lines is practically certain to bring forward a considerable amount of useful information, alike for the purposes of improved methods of insurance administration and the needs of the community at large.

It would carry me entirely too far to even briefly discuss the elements of *climate* in their relation to human mortality. Most of the works on climatology give very superficial consideration to the question of health. It has been pointed out in a recent editorial in the *British Medical Journal* (April 6), in a review of a notable work on the Climate of Africa, that "it is a great pity that the healthiness or unhealthiness of the different colonies or protectorates, that is, the medical status of each place, was not equally dealt with." This conclusion applies to most of the works on climate, including the treatise by Ward and the earlier work by Ham. The investigations of Dexter on "Weather Influences" would seem to prove quite conclusively that there are definite physiological effects of certain meteorological conditions, and as emphasizing the object in this field of research, reference may be made to a recent and admirable paper by Dr. Gordon on the "Influence of Strong Prevalent Rain-Bearing Winds on the Course of Phthisis." This investigation would seem to prove that exposed parishes have a decidedly higher proportion of comparatively short cases of phthisis than the sheltered parishes and a lower proportion of cases of comparatively long duration. In its broader aspects the subject of climate is of importance, in view of the rapidly increasing population of the United States in the humid regions of the South with a high dew point and in the elevated regions of the West at altitudes of over 2,500 feet. In the more restricted consideration of the climate and health of hot countries, it requires to be said that within recent years many valuable contributions have been made to the subject of tropical climatology, but the available statistical information has been utilized to only a very limited extent. The investigations of Woodruff on the "Effects of Tropical Light on White Men" open a new field of discovery in a most promising direction. His observations on actinotherapy are decidedly suggestive, but further research is required to establish Woodruff's conclusions by means of a more decisive array of facts. The experience on the Isthmus of Panama and in many other intensely tropical countries has shown that it is not impossible to control most of the health-destructive factors which menace the white race in hot countries, but there is serious danger of erroneous conclusions on account of only apparently satisfactory results. Considering the extreme mobility of modern populations, together with the more generally accepted conformity to rules for residence in the tropics, the temporary and permanent effects of tropical residence may not in their entirety become a matter of statistical record. The tropical death rate of white populations fails to reflect precisely the full effect of tropical residence, since an ever-increasing proportion return to temperate regions for the recovery of health or the prevention of physical deterioration. A much longer period will be required to establish the truth of the assertion that residence on the Isthmus is to-day absolutely free from health-injurious consequences, and in any event it may safely be asserted that the Isthmus is not a health resort for Americans at the present time. The sanitary progress which has been made challenges the admiration of the world, but it may do serious harm to overdraw the conclusions based upon a superficial study of the facts.

The *geography of disease,* or geographical pathology, furnish subjects of research which are bound to attract much more attention in the future than in the past. The classical works by Hirsch and Davidson have been followed by a most useful treatise by Dr. Clemow, who gained much practical experience as British delegate to the Ottawa Board of Health. An excellent summary account of health progress and health administration in the West Indies has been published within a year or two by the late Sir Rupert W. Boyce, Dean of the Liverpool School of Tropical Medicine. Increasing attention is being given to the subject in the official reports of governors and medical officers of the tropical possessions of European countries and the United States, but special mention requires to be made of the excellent medical reports for the German tropical possessions in East and West Africa, Cameroon, New Guinea, etc. It is to be hoped that the contents of these reports will be made more accessible to English readers through the "Annals of Tropical Medicine," published under the direction of the Wellcome Laboratory at Khartoum, in the British Soudan. The scientific Memoirs of this laboratory are among the most encouraging evidences of the sanitary control of tropical countries, which is reflected in a gradual fall of the death rate of the white population, a decrease in some respects, however, more apparent than real.

The field of *tropical medicine* is immense, but one of considerable practical importance to American life insurance companies, on account of the ever-increasing proportion of American residents temporarily or permanently residing in the countries of the Torrid Zone. The general death rate of India has been reduced to 30.9 per 1,000 in 1909, but the rate for the Christian population only was 19.4 per

1,000. The principal cause of mortality is fevers, chiefly malarial, accounting for a death rate of 19.8 per 1,000 in 1909, followed by a cholera death rate of only 1.06. The highest death rate from cholera during recent years occurred in 1900, when it attained to 3.8 per 1,000, and the highest death rate from plague occurred in 1907, when it reached 5.2 per 1,000. In due appreciation of the great practical importance of sanitary reforms, the government of India has actively interested itself in preventive measures, and in 1909 an important scientific Memoir was published on "Malaria in India," followed in 1907 by an exceedingly instructive report on the "Causes of Malaria in Bombay," and suggestions for measures of sanitary control. Reference may be made to the work of the Liverpool School of Tropical Medicine, which in 1903 published the results of the "Malaria Expedition to the Gambia," followed by equally suggestive reports on "Anti-Malaria Measures at Ismalia," the "Distribution and Control of Sleeping Sickness in the Congo," "Yellow Fever Prophylaxis in New Orleans," etc., etc.

The admirable sanitary results of the Japanese occupation of Formosa emphasizes possibilities of the greatest practical importance. The mortality of Formosa, for illustration, has been reduced for Japanese residents from 20.1 per 1,000 in 1906 to 16.8 in 1909. The local incidence of malaria has been determined by means of a bacteriological survey for every section of Formosa and also the geographical distribution of malaria-carrying mosquitos. For nearly every tropical country under European or American administration to-day, the available records indicate at least a fair measure of sanitary progress achieved during recent years. The European death rate of Egypt has been decreased from 18.9 per 1,000 in 1902 to 13.5 per 1,000 in 1910. In Hongkong the malaria admission rate for European troops has been reduced from an average of 625 per 1,000 during the four years ending with 1904 to 228 per 1,000 during the six years ending with 1910. The death rate of Calcutta for 1910 was 26.7 per 1,000, or the lowest recorded mortality for twenty years. In the Island of Ceylon the death rate of Europeans has decreased from 20.6 per 1,000 during the decade ending with 1908 to 15.6 per 1,000 during 1909 and 13.7 for 1910.

The average death rate of Americans in the Philippine Islands was 11.1 per 1,000 for the five years ending with 1911. Granting that most of the Americans are of the age period when the normal death rate would not exceed 8 or 9 per 1,000, and that a fair proportion leave the Islands while impaired in health as the result of tropical residence, it is a safe conclusion, sustained by abundant evidence, that by conformity to well-established rules it is not a difficult matter to preserve health in the Philippines at the present time. The death rate for all races continues high, having been 37.2 per 1,000 during the period under consideration, and it is particularly suggestive that the mortality from beriberi should have increased from 1.8 per 1,000 in 1907 to 6.2 in 1911. Cholera, leprosy, malaria and dysentery are decreasing, and there is abundant evidence, official and otherwise, that with respect to sanitary control the Philippines are to-day as well, if not better, administered than our Southern States. The present occasion does not permit of a more extended survey of the sanitary progress of American tropical possessions, but from every source the evidence is quite conclusive that the deliberate efforts of recent years have been productive of excellent results and that the menace to health and life of American residents in tropical countries is decidedly less at the present time than it was a generation ago. In no direction, however, are there more promising opportunities for practical research work than in the field of tropical medicine and tropical mortality, and to no interest are such results of greater practical importance than to the life insurance companies of the United States.

There is most urgent need for the establishment and proper equipment of a School of Tropical Medicine after the model institutions of Liverpool, London, and Hamburg. Such a school, by preference, should be located at New Orleans, where a practical beginning has been made in connection with the Medical Department of Tulane University and in cooperation with the Charity Hospital. With the opening of the Panama Canal there can be no question of doubt but that the port of New Orleans will become the most important commercial outlet for the trade of the United States with the countries to the south. With an increasing water-borne traffic, the risk of the introduction of tropical diseases will become a more serious one to the nation, and for the study, as well as for the prevention of such diseases, a well-equipped School of Tropical Medicine is one of the most urgent needs of the present day. A brief reference only requires to be made to the still considerable prevalence of malaria throughout the South, to the sporadic occurrence of cases of leprosy, Oriental sore, etc., and the menace of a further spread of pellagra, which in the registration area alone in 1910 accounted for 368 deaths. The work of the Rockefeller Sanitary Commission for the Eradification of Hookworm Disease indicates the practical direction of sanitary research. The number of persons treated for hookworm disease on behalf of the Commission was 140,000, and according to a survey of 125 counties, the disease was most prevalent in North Carolina, Mississippi, South Carolina, and Georgia. It requires no argument to prove that work of this kind must needs be of practical value to life insurance companies and that the expenses incurred have been justified by the results.

In the field of *anthropology* the opportunities for research are practically boundless. As yet only a beginning has been made, and the textbook on the "Races of Europe," by Ripley, for illustration, may be referred to as evidence of the inadequacy of our present understanding of race traits and characteristics in their relation to disease resistance and longevity. Anthropometric measurements are not available for sufficient numbers, and the details of mortality by causes and with a due regard to sex and age are not available for qualified statistical analysis. The population of the United States includes to-day so large a variety of types of mankind that both anthropology and anthropometry occupy a much higher place in American political and economic science than heretofore. It is a matter of regret that the extensive investigations of the United States Immigration Commission should not have included observations in detail of the physical and pathological peculiarities of the foreign elements which have come to this country in such large numbers during recent years. The observations by Boaz, however, may be referred to as an indication of the direction which such in-

quiries are bound to take if anthropology is to be made useful for practical purposes. Racial, as well as interracial, problems have their place in life insurance to-day. The vast amount of mere opinion or conjecture requires to be replaced by trustworthy statistical data.

The precise methods of Duckworth, as adopted for his studies in the Anthropological Laboratory of Cambridge, should be applied to the scientific study of the foreign element in the United States. The thoroughly scientific contribution to the racial anatomy of the Philippine Islanders, including new methods of anthropology, should be made use of in similar research work in the United States. The proceedings of the First Universal Races Congress prove conclusively that as yet not much more than a beginning has been made to raise anthropology to the status of an exact and applied science. The ethnographic studies made in connection with the Census of India, particularly by Risley, foreshadow the direction which such investigations should take in the United States. The work by Hrdlicka on the North American Indian is a valuable contribution to a subject which as yet has been largely neglected. What is true of the foreign element and the non-Caucasian races in the United States is equally true of the natives. The researches by Baxter and Gould into American anthropometry have not been followed for half a century, although the conclusions then arrived at were of exceptional scientific and practical value. There is, however, a large amount of anthropometric data in the archives of insurance companies which could be utilized for the purpose of a national anthropometric survey. Sooner or later the question of national physical progress or deterioration will require qualified consideration. At present many of the conclusions as to what constitutes normal physical man or normal woman, and what constitutes the normal rate of physical growth according to age and sex are mere matters of conjecture.

The comparative mortality rate of the white and colored races of the United States may be referred to as a practical illustration of the importance of research work in the field of *race pathology*. The average death rate of the white population of ten southern cities during the period of 1906-1910 was 16.7 per 1,000, whereas the corresponding death rate of the colored population of these cities was 30.6 per 1,000, or 75.4 per cent. in excess. The tuberculosis death rate of the white population was 18.8 per 10,000, whereas the corresponding tuberculosis death rate of the colored population was 49.8, or 164.9 per cent. in excess. The highest death rate for the white population was considerably below the lowest death rate for the colored population, and the highest tuberculosis death rate of the white population was 22.9 per 10,000, or still considerably below the lowest tuberculosis death rate for the colored, or 28.2. The true incidence of an excessive death rate is only disclosed by an analysis of the mortality in detail, with a due regard to age and sex. It is to be hoped that the Census Office will see its way clear to publish in the near future a full account of the mortality of the several races and at least the more important foreign elements in the United States, by sex, cause, and divisional periods of life. It is true that such an analysis involves a large amount of clerical labor, but the results would be most useful for the social and economic needs of the nation.

Aside from racial and climatic factors there are *the bio-sociological factors*, particularly sex, matrimonial condition and fertility, which cannot be considered on this occasion. A brief reference may be made, however, to a very suggestive recent discussion of the mortality of eldest children in large families by Lucien March in the *Journal of the Royal Statistical Society*, which would seem to sustain the conclusion that the death rate of last-born children is higher than the mortality of first-born children. The discussion raises the whole question of the so-called Bremersche-Belastung, which by foreign authors has been discussed in some detail with reference to tuberculosis. Even granting that there is an increase in mortality with the order of birth, it, of course, does not follow that such a conclusion could be applied to practical purposes in life insurance medicine. It, however, is feasible to take such facts into account, provided they are sustained by incontrovertible evidence. It is generally admitted that the mortality of the married is more favorable than the mortality of the unmarried, but even with regard to this question much more trustworthy statistical data are required than are as yet available. Even the question of sex difference and the apparently higher mortality of insured women than insured men, in contrast to the lower death rate of women in the general population when compared with men, is a field of statistical research which has not received the attention of which it is deserving.

There has been much speculation from time to time as to *the most fatal year of life*. One quite learned discussion in the London *Evening Standard* some years ago fixed the age at 37, while, according to an article in the New York *Times*, 56 would seem to be the fatal year for persons of genius. Lord Beaconsfield appears to have been the author of the remark that 37 was the fatal age, and it has been held that this observation was sustained by much striking testimony as to its truth. Without disputing, on this occasion, the contention with reference to men of genius, it may be stated as a matter of fact that the maximum number of deaths in adult life, according to American experience, occur in the 66th year. This conclusion, derived from the vital statistics of the Census, is practically confirmed by the experience of a large industrial insurance company, according to which the largest number of deaths of males occur at the 65th year of life and of females at the 64th year. The small differences may be accounted for by the method of stating the age at death, as to whether next birthday, or nearest birthday, or more precisely by reference to months and days. There is, however, a distinct but variable rise in the actual number of deaths of males at ages 23, 31, 36, 41, 46, 51, 56 and 61, which would seem to indicate by the regularity in the periodicity that the result is partly influenced by the method of returning the ages at death. Be that as it may, the data are decidedly suggestive, and the conclusion remains unshaken that the probable age of greatest frequency in the actual number of deaths, or the year of adult life at which most deaths occur, in the United States, is about 65 or 66.*

There is one phase of the mortality problem to which there appears to be no reference in the textbooks on life insurance medicine. The late Sir James Paget pointed out that there is apparently a

*It is not at all settled that the death rate increases with every year of adult life and it is quite probable that the rate is higher at 20-24 than just before or after.

chronometry in life as well as in chemistry or mechanics, and that in the study of pathology insufficient consideration is given to the question as to how much of exact disease or of its variations may be the result of a serious disturbance of the time rate at which the organic processes should be discharged. As observed in the MEDICAL RECORD of May 31, 1902, "There is much reason in the argument that many cases of failure in health are due to these errors in the chronometry of life," and the Record quotes the conclusion of Sir James Paget, that "Pathology and sometimes our practice would be improved if local defects of working power were more often thought of as errors in the time rate of life in the defective objects and if we would think that the age of each object is not always wholly or exactly expressed by the time that has elapsed since it was first formed," and, furthermore, "If we would bear in mind that any internal organ may deviate from the general time rate of the body as much as the teeth, the hair, and the skin, which we so commonly think of as old before their time." In other words, the question should not be as to the absolute age, but as to the attained age of the heart, the brain, or any other part of the body, which may seem to be less healthy than the rest.

To this important suggestion, which obviously must be of much practical importance, if it is at all applicable, to the needs of life insurance companies, a brief reference may be made to another and equally new observation by Minot, that "We must, it seems to me, conclude that longevity, the duration of life, depends upon the rate of *cytomorphosis*. If that cytomorphosis is rapid the fatal condition is reached soon, if it is slow the fatal condition is postponed. And cytomorphosis in various species and kinds of animals must proceed at different rates and at different speeds at different ages." A discussion of this suggestion would involve the whole question of the cell and its basic function in the economy and the duration of human life. Such a discussion obviously falls within the technical qualifications of the expert in embryology and cellular pathology.

There has been much speculation during recent years as to the probable *effect* on the average duration of life *of the elimination of specific diseases*, such as tuberculosis, yellow fever, smallpox, etc., or at least of their substantial reduction. Farr, in 1875, anticipated this problem by a discussion of the effect of the extinction of any single disease on the duration of life. But long before Farr, Duvillard had calculated the probable effect of the elimination of smallpox as the result of vaccination, which, he concluded, would add three and one-half years to the existing mean lifetime. Modern writers have been chiefly concerned with the effect of average longevity as the result of a diminution in the mortality from tuberculosis and typhoid, and some very interesting calculations have been presented by learned authorities whose work is deserving of more general appreciation, as a practical contribution to the economic consideration of public health questions. Further inquiry of this kind would unquestionably lead to some practical conclusions and perhaps no other data would more fully justify the cooperation of life insurance companies with the nation-wide movement for an improvement in public health.

There is probably no disease other than tuberculosis of greater practical importance to life insurance companies as a menace to the future interests of their policyholders than *cancer*. Whether the increase in the rate is real or only apparent, it is evident that the mortality from cancer constitutes a very substantial proportion of the mortality from all causes at ages 45 and over. Cancer research is, therefore, one of the most promising fields of inquiry, and what has been done in this respect in England, Germany and Hungary suggests a similar and nation-wide investigation for the United States. The work of the Cancer Commission of Harvard University and of the Cancer Laboratory of the New York State Department of Health must be considered to be of great practical value to life insurance companies and to life insurance medicine. It is suggestive that a painstaking statistical study of cancer death rates, based largely upon American data, should have been made by Dr. Maynard of Pretoria, South Africa, but the most comprehensive statistical reports on cancer and the essential factors of its occurrence are those published by the Royal Statistical Bureau of Hungary and the Municipal Bureau of Statistics of Amsterdam. The largest number of deaths from this disease in the United States occur at ages 60 to 64, when 14.2 per cent. of the mortality of males and 12.8 per cent. of the mortality of females is the result of this specific cause.

The relative frequency of *cancer by organs* affected has been as follows for the United States, for the period 1900-1908: For males the mortality of cancer of the mouth was 3.3 per 100,000 of male population; of the stomach and liver, 24.4; of the intestines, 6.1; of the skin, 3.0; and all other organs or parts, 13.8. The total death rate from cancer for males was 50.5.

For females the mortality from cancer of the mouth was only 0.8 per 100,000 of female population; of the stomach and liver, 25.7; of the intestines, 8.6; of the skin, 1.8; of the breast, 11.5; of the organs of generation, 20.2; and for other organs and parts, 16.7. For the total female population the rate was 85.3 per 100,000.

The most suggestive recent statistical study of the cancer problem is by Dr. C. E. Green, of Edinburgh. This author adopted entirely original methods of research, based, however, largely upon statistical investigations. He made the necessary corrections of cancer death rates on account of the admission of non-residents to hospitals in large cities, and his conclusions are quite startling, but apparently are well sustained by the available evidence. In brief, he brings out a traceable relation between cancer occurrence and topography and occupation, concluding in part that "The towns lying in a cup have by far the highest cancer mortalities, while those on a level site with level surroundings show the lowest percentage. Those on hill sites are slightly higher than those on sloping sites."

I obtained, through the courtesy of the United States Geological Survey, a grouping of American cities conforming to the topographical division adopted by Dr. Green, but the corresponding cancer death rates did not exactly conform to his conclusions. I would partly attribute this result to the inherent defect in all our cancer mortality statistics, in that the deaths of non-residents were included with those of residents in the municipal mortality returns. It is quite possible that if the method of Dr. Green were followed in its entirety, the conclusions for American communities would at least partly conform to his own, but it requires to be considered that we have a much more mobile

population in the United States than is common to the large and medium size cities of Scotland, so that the degree of exposure to possible local cancer-producing conditions would be much less in the United States. The work of Green emphasizes the practical utility of original statistical research in the field of medicine, and particularly in that branch which concerns itself chiefly with the successful solution of life insurance problems.

The most gratifying evidence of American sanitary progress is to be found in the gradual, but persistent, reduction in the death rate from *typhoid fever*. In 1891 the typhoid death rate for American cities was 59.0 per 100,000 of population, against only 20.2 in 1910. The decrease has been progressive by five-year periods, from 45.4 per 100,000 during 1891-1895, to 25.3 during 1906-1910. In Northern and Western cities the rate has decreased from 43.1 during the first five years of the period, to 23.4 during the last. In Southern cities for the white population the rate has decreased from 55.4 to 37.2, and for the colored population from 73.9 to 51.0.

Regardless of the sanitary progress which has been made throughout the country at large, the typhoid rate continues unduly high in certain sections and dangerous outbreaks occur in localities heretofore considered secure. The intimate relation of typhoid fever occurrence to polluted water supplies is no longer a matter of conjecture, but it is an established fact. The research work into the origin and prevalence of typhoid fever in the District of Columbia and a number of other badly infected localities throughout the United States, by the Public Health and Marine Hospital Service, discloses precisely the underlying causes of a strictly preventable disease.

I can only make a very brief reference to *tuberculosis*, with regard to which it may be said that the death rate for American cities has decreased from an average of 32.3 per 10,000 during the five years ending with 1874 to an average of 18.5 for the five years ending with 1909. The statistical laws of tuberculosis are far from being as definitely understood as would be desirable for life insurance purposes, and this holds true particularly for the experience data of tuberculosis sanatoria. These records, with few exceptions, have not been made the subject of proper tabulation and critical analysis, but the aggregate experience would be a most useful addition to medical and insurance science. Among the factors which, among others, require consideration, are the age on admission for treatment, the Turban stage of the disease on admission and its previous duration, the lung involvement, the average weight on admission and discharge, the value of the tuberculin treatment, the history of exposure to infection, the family history, and, most of all, the post-discharge results. For German sanatoria an admirable analysis of the aggregate institutional experience is published each year and in much detail for each of the thirty-one invalidity insurance offices, providing systematic treatment of tuberculous members, almost entirely of the wage-earning class. The statistical investigations made at Saranac and Liberty, N. Y., Washington, D. C., and Fort Bayard, N. M., etc., are deserving of mention, but as yet our American data are not collected on the basis of a uniform schedule and subjected to a critical analysis, nor, as a rule, are the post-discharge results observed in the proper manner to provide a basis for trustworthy conclusions as to the medical value of sanatoria treatment and its relation to the expense incurred.

The relation of *eyestrain* to mortality and morbidity has been made the subject of painstaking inquiry by Dr. George M. Gould and others, whose investigations prove quite conclusively that defects of vision are often important contributory causes in the more obvious diseases which shorten life. It may be impracticable to require insurance applicants to wear suitable glasses for the correction of visual defects, but it may be suggested that some advantage would accrue from the inclusion of a question as to vision in the application blank.

Much progress has been made in the field of *industrial diseases*, but much requires to be done to provide life insurance companies with really trustworthy information as to what really constitutes an occupation detrimental to health. The field of specific occupation diseases is quite limited, since the predominating causes of ill-health in industry are much the same, except in an exaggerated form, as among the population at large. The distinct field of occupational neuroses has been admirably reported upon, with details of the clinical study of one hundred cases, by Dr. Charles L. Dana of New York. The investigation forms an admirable basis for further inquiry, and, as pointed out by Dr. Dana, by those, not necessarily physicians, but who are interested in industrial diseases. The subject within recent years has attracted much qualified attention on account of its relation to workmen's compensation and employers' liability laws, and the results of individual or collective investigations are not only of much interest to the State but also to life insurance companies in the more careful selection of risks.

Mental afflictions, or *unsoundness of mind*, especially in their relation to the mortality from nervous diseases, are a much neglected field of statistical inquiry. The evidence is not conclusive whether insanity is on the increase, particularly because of the difficulty of a precise definition as to what constitutes unsoundness of mind. The statistics of institutions for the treatment and cure of insane persons require to be made the subject of a much more qualified and uniform tabulation and analysis than has heretofore been the case. Possibly no field of statistical research is of greater interest to the student of social pathology. As regards the heredity of insanity, the same conclusion probably applies as in the case of tuberculosis, that it is not the defect itself which is inherited, but a lesser resistance against conditions destructive of soundness of mind. There have been innumerable attempts at the classification of insanity, but equally innumerable reasons have been advanced why a definite and final classification seems almost impossible. It is held by Haviland Hall, the well-known author on medical examination for life assurance, that "The influence of the mother's insanity is more serious than that of the father." As far as I have been able to learn, there is no substantial statistical basis for this conclusion. The same conclusion applies to the alleged heredity of suicide, although there are strong reasons for suspecting a traceable relation between suicide in the parents and a tendency to suicide in the offspring. The suicide rate has persistently increased in American cities, from an average of 14.5 per 100,000 of population during the five years ending with 1895 to 20.0 during the five years ending with 1910. The

suicidal impulse, it has been pointed out by Clouston, "constitutes the great peculiarity and the special responsibility attaching to the depressed form of mental unsoundness." There is, therefore, a close relation between insanity and suicide, which emphasizes the importance of further research in the field of neurology and abnormal psychology.

Much valuable information would be derived from trustworthy *records of disease*. Many years ago a beginning was made to collect such records under the auspices of the New York State Medical Society and subsequently the State of Michigan inaugurated a system of weekly reports of sickness from health officers, under the direction of the late Dr. Baker. In 1876 Dr. Draper of Boston in the Report of the Masschusetts State Board of Health, contributed a suggestive discussion to the subject of Registration of Prevalent Diseases, and a Bureau of Health Correspondence was established, but the history of the movement is not a matter of record. By far the most suggestive and philosophical discussion of the value of registration of disease is contained in "Essays and Papers on Some Fallacies of Statistics Concerning Life and Death, Health and Disease," by Dr. Rumsey, published in London in 1875. About twenty years later Dr. Arthur Newsholme, now the Medical Officer of the Local Government Board, read an address on a "National System of Notification and Registration of Sickness" before the Royal Statistical Society, which is a most useful and suggestive contribution to the subject. This was followed in 1897 by a small treatise on "Wasted Records of Disease," by Charles E. Paget. All of these efforts may be summed up in the statement that a clear case has been made out for the utility of such records, but it is self-evident that unless there is an earnest and intelligent cooperation of the medical profession, the practical results must be very limited. From a life insurance point of view, the accurate and complete registration of general sickness would prove a most useful addition to knowledge and emphasize much more precisely than mortality records the local causes responsible for ill-health. The present opportunity is not suitable for the discussion of the technical difficulties which at first may seem insuperable, but I am quite confident that, considering the success which has been achieved with the notification of infectious diseases, the time is bound to come when all diseases and surgical operations will be made a matter of record.

The fallacies inherent in *crude vital statistics* have been so clearly apparent for many years that it is difficult to understand why obvious errors should continue to mislead the seeker after truth. The forced elimination of secondary or contributory causes of death involves the use of more or less arbitrary methods of statistical classification, which are recognized by most registration officials, but done away with by none. The difficulty is met by the use of the Budapest system of death classification, the value of which is as yet but very imperfectly recognized in the United States, including registration officers and life insurance companies. The utility of this method is shown to best advantage in a study of the mortality from diseases of the heart and urinary organs, and also in alcoholism and diseases of the liver. In fact, there are few deaths without more or less important complications and a thorough understanding of the mortality problem is out of the question until secondary or collateral causes are also taken into account. It may sound paradoxical, but it is true, that it is seldom that persons actually die of the disease which leads to death. It is also true that the whole subject of *death* has only within recent years attracted scientific attention and most of the earlier essays and works on death and the prolongation of life are of small intrinsic value. Reference may be made to the very suggestive essay on "Thanatology" by Dr. Roswell Park of Buffalo. Innumerable tests have been suggested for the positive diagnosis of death, but there has not been much advance in this direction since 1746 when a very interesting treatise on "The Uncertainty of the Signs of Death" and the "Danger of Precipitate Interments and Dissections" was published, with numerous illustrations of persons supposed to be dead and with some illustrations of persons restored to life. The ancient practice of long-delayed interment may find its justification in the uncertainty of the signs of death, although the classical treatise by Brouardel on "Death and Sudden Death" would seem to suggest abundant means for the prevention of what cannot but be considered the most awful possibility of human existence.

The literature of longevity and *the prolongation of life* is large and constantly increasing. The researches of Metchnikoff and others have placed the whole subject upon a sound and scientific foundation. The discourses on the "Means for the Prolongation of Life" by Sir Hermann Weber emphasizes the fundamental principle as regards conduct, that "work and moderation are the main source of health, happiness and long life." There is less mystery in longevity to-day than in former years and the conclusion is gaining ground that the attainment of normal old age is largely a matter of conformity to well-established principles not difficult in their application. There is much disutility in the argument that the average duration of life is increasing, since the gain which has been made primarily affects the younger ages. The chief concern is the preservation of adult life, which is of the highest social and economic importance to the State. The attainment of extreme longevity need not be a matter of much serious concern, but there would seem to be some evidence that the number of centenarians is increasing, but, as shown by Young, the numerous alleged cases of extreme longevity require to be viewed with suspicion, in the absence of really trustworthy documentary evidence as to the date of birth. The mere attainment of old age without the preservation of all the faculties is rather a hindrance to human progress than a help. As pointed out, however, by Dorland in his admirable discussion of the "Age of Mental Virility," "some of the greatest men and minds of all ages have attained to old age and some of the greatest works of genius have been produced after the age of 70 years." Opinions may differ as to the specific cause of old age, but progress is being made toward a better understanding of the contributory causes, at least, which shorten life and bring about premature senility. Metchnikoff's conclusion is that intestinal putrefaction shortens life in the large majority of cases of adults and that lactic acid is a means of preventing such putrefaction as shown by experiments on men and mice and by the comparative longevity of races using sour milk. There can be no question of doubt that autointoxication requires to be recognized as of much greater importance than is now generally assumed and it may serve as an explanation of many deaths attributed,

more or less erroneously, to so-called acute indigestion. If it is true that lactic ferments have been advantageously employed in cases of cancer of the stomach, Bright's disease, rheumatoid arthritis, etc., it is obvious that there are vast opportunities for the future prolongation of adult life which have heretofore been neglected.

In its final analysis, the true cause of premature death is largely a question of erroneous habits of life. It is certainly suggestive that the proportionate mortality from nervous and urinary diseases should be so decidedly excessive among persons of heavy weight. The same is true also for rheumatism and diabetes. It has properly been said that few persons take the diet best suited to their requirements, and the sum and substance of sound advice has been summed up by Sir Hermann Weber in the following rule:

"Observe moderation in food and drink and all other physical pleasures. Breathe pure air at all times. Take regular daily exercise, whatever the weather. Go to bed early and rise early. Take a daily bath and let the skin be well rubbed. Perform work regularly and cultivate a hopeful or optimistic disposition. Avoid alcohol and other stimulants and narcotic drugs, and finally make a resolute effort of will to preserve health and life."

The field of life insurance medicine today includes not only the primary function of risk selection, but also the conservation of human life in the individual and in the mass. Certain companies have gone so far as to publish pertinent suggestions with regard to the preservation of health and life to their policyholders, while the Association of Life Insurance Presidents has inaugurated preliminary measures for a sanitary survey of the United States. Some of the fraternal societies have established institutions for the treatment of chronic wasting diseases and one of the largest companies has commenced the issue of a quarterly publication devoted to the human conservation problem, as it affects life insurance policyholders in particular, and amplified by definite instructions in matters of personal hygiene. As said in an editorial in the *Journal of the American Medical Association,* with regard to this movement, "It is an evidence of the wisdom and progressiveness of the insurance companies to combine considerations of humanity with good business policy." Considering the vast importance of life insurance institutions to the public and the State, it is of the utmost importance that whatever is done should be done rightly at the outset, so that the faith of the people in the superior medical administration of these companies may not be shaken by the results of ill-advised experiments.

The function of general and even experimental research in the field of life insurance medicine becomes, therefore, a duty, which I have tried to emphasize in a few matters of detail and with a due regard to the difficult situation which confronts the companies in combining considerations of humanity with considerations of business necessity and business policy.

Chloride Retention in Exudative Processes of the Skin.—V. Menschikoff has found that children with the exudative diathesis react with a greater retention of chlorides than normal children. An increased ingestion of sodium chloride has no effect on the cutaneous manifestations. Children with manifest signs of the exudative diathesis show greater variations in the chloride metabolism than children with a latent exudative diathesis.—*Monatsschrift für Kinderheilkunde.*

ACCESSORY PANCREAS IN THE GASTRO-INTESTINAL TRACT.*

By C. L. GIBSON, M.D.,
NEW YORK.
SURGEON ST. LUKE'S HOSPITAL.

The presence of misplaced islets of pancreatic tissue in various parts of the gastrointestinal tract was first described by Klob (*Zeitschrift der Gesselschaft der Aerzte zu Wien,* 1859). Since then quite a number of observations have followed and Opie describes quite fully ten instances found in eighteen hundred autopsies at the Johns Hopkins Hospital. This fact and other important data contained in this article are taken from the valuable treatise of Opie on the Pancreas, second edition. Until quite recently the occurrence of an accessory pancreas was looked upon as of little practical significance, its existence being demonstrated as an incident of post-mortem findings.

Opie says "A true accessory pancreas is a mass of pancreatic tissue wholly separated from the pancreas and provided with a duct of its own. Such isolated masses of glandular tissue derive some importance from the possibility that they may perhaps vicariously assume the function of the main organ when it is diseased and that they may cause diverticula or hernia of the intestinal wall. They may be divided into two groups—those situated above the pancreas in the stomach and duodenum and those below the gland in the duodenum and jejunum.

"Small masses of aberrant pancreatic tissue are usually about 1 cm. in diameter, one is described as 4.5 x 3.5 across and 1 cm. in thickness. More than one may occur in the same individual."

Pathological changes affecting accessory pancreatic tissue. Opie speaks of fat necrosis occurring about an aberrant nodule. Also "the isolated nodule tends to produce chronic interstitial inflammation, and interstitial tissue is almost constantly present in greater quantity than in the normal gland." Inflammatory changes are probably dependent upon occlusion of the minute often tortuous ducts and are doubtless intensified by invasion of bacteria from the stomach or intestine.

The following case of aberrant pancreas was observed by me in June, 1909:

Miss F., age 25, milliner. Family and previous history unimportant; has never been in very good health. For the past two years she has had stomach trouble, characterized by epigastric pain, occasional vomiting, on one occasion of blood. The pain comes somewhat periodically, but is increasing in frequency and intensity, so that she is prevented from pursuing her occupation. She is somewhat pale and anemic; physical examination was negative except for some tenderness in the right hypochondrium.

I saw her in one of the attacks of pain, an unusually severe one, in which she gave every appearance of a person suffering from biliary colic. An exploratory operation was finally decided on, the presumptive diagnosis being cholelithiasis or gastric ulcer, or both.

At operation a circumscribed, slightly elevated, well marked tumor about the size of a quarter was found an inch proximal to the pylorus on the anterior wall. It was excised. The patient made a good surgical recovery and for some months the stomach symptoms were alleviated but returned, though perhaps not quite so severely. Her general condition remains poor.

The gross examination of the specimen showed

*Read before the Practitioners Society, May 3, 1912.

on the mucous surface a rather racemose conformation with a central opening as of a duct. Although I said at the time that it looked like a gland, the true nature of the condition which should have been apparent at once, if one had the condition in mind, escaped me as well as several observers. In fact, from one pathologist we had a microscopic report as adenocarcinoma.

The final report is as follows:

Diagnosis: Aberrant pancreatic tissue in the stomach wall.

Macroscopical examination: Ulcer of stomach. Specimen consists of flat oval piece of stomach wall, 2.5 x 2 x 0.5 cm. Section cut through one ragged edge and through a small nodule at one part.

Microscopical examination: Section through nodule shows masses of epithelial cells which to a faint degree simulate in their arrangement glandular tissue packed closely together with almost no stoma. There are many cysts and ducts lined with high glandular epithelium, which itself is occasionally filled with mucus. Both the adenomatous tissue and the closely packed cells lie in the muscularis. No mitoses found. The general structure of the epithelial masses suggests the pancreas, and though no islands of Langerhans can be found the tissue is probably pancreatic. The ducts and cysts also render this diagnosis probable. The mucosa of the stomach is not normal. There is considerable growth of epithelial cells in the mucosa, probably a portion of the pancreatic nodule. There is no reason to consider the specimen an adenoma or a carcinoma.

Various forms of examinations had been made before operation. An *x*-ray (bismuth) of the stomach seemed negative, but with the findings in mind the plate was reviewed and showed at the site of the pancreatic lobule a thinner and shadowy appearance which, with our greater experience to-day, would be suggestive of a pathological process.

Frankly, I doubt if this pancreatic lobule accounted for the patient's symptoms, particularly as it did not impinge on the pylorus. That such a lobule may cause mechanical obstruction if rightly situated is evident from the following case,* some of its features resembling Miss F.'s condition.

Man, 37, gastric symptoms two years, increasing severity in past three months, attacks of severe pain like biliary colic. At operation a tumor size of a large pea was found within the pylorus. Supposing it to be a growth, the pylorus was resected. Temporary relief, later return of symptoms. Examination showed that the tumor blocked the pylorus; it was an adenoma of an aberrant pancreatic lobule.

The authors state that they have been unable to find a similar case, but I am inclined to think that I had some years ago such a condition which in my ignorance of the subject I failed to recognize.

The patient was an elderly man, much reduced by a supposed carcinoma of the stomach. An exploratory operation showed the presence of a somewhat movable rounded mass the size of a small cherry springing from the anterior wall of the stomach close to the pylorus. Removed by incising the stomach, being nearly pedunculated. Relief of symptoms, restoration to health.

I believe now this condition might have been demonstrated to be pancreatic tissue, as it quite closely resembled the case just quoted.

The great bulk of these pancreatic lobules are situated in the different parts of the small intestine. Some of them are located in the usual site of the Meckel's diverticulum, that is in the last two feet of the ileum. In many, perhaps most cases, they form a diverticulum which apparently closely simulates a Meckel's diverticulum, and may give rise to pathological changes of importance, as may be judged by the following case reported by Mr. Alexis Thomson.

"*Acquired Diverticulum of Lower Ileum with Accessory Pancreas Causing Symptoms of Acute Appendicitis.*"—Man, 53 years old, acute symptoms, temperature 103°—operation. A small amount of clear serum escaped, appendix apparently healthy. About eighteen inches from the ileocecal valve a diverticulum was found of the "finger of a glove" type, presenting a bulbous enlargement resembling in shape the penis. Its peritoneal coat showed a thin deposit of fibrin, but no undue vascularity. Uneventful recovery.

Description of the specimen: The diverticulum in the contracted state (due to fixation in alcohol) measured 3 centimeters in length; the tubular portion measured 1 centimeter in diameter, while the club-shaped extremity measured 1.3 centimeter. The tubular portion presented the appearance of normal small intestine, the club-shaped portion appeared to be composed of fat; there was a hollow constriction intervening between the two portions. On section the club-shaped portion was seen to be solid and to constitute fully one-half of the entire diverticulum, its center presented a lobulated appearance, as if composed of gland tissue, while the cortex consisted of fat. . . . At the distal end of the tubular portion and confined within the longitudinal muscular coat is a minute, well-defined mass of pancreatic tissue, the lobules of which are arranged as in the normal pancreas, and are provided with an average number of ducts. . . . Transition forms are also met with between the most minute of the newly formed ducts, and the solid masses of the cells which give the cancerous appearance to the parts thus affected.

The clinical features of the case just described have put me in mind of a case operated on as a Meckel's diverticulum, the gross appearances quite closely duplicating Mr. Thomson's description. No microscopic examination was thought of then; in the light of our more recent investigation such are now imperative and may increase our knowledge.

From the embryonic standpoint diverticula due to accessory pancreatic islets should be limited to the small intestine. We do see great misplacements of other tissue such as the adrenals in unexpected places, and I have been led to speculate whether some of the diverticula of the larger intestine, particularly of the sigmoid, might not owe their origin to such a cause.

72 East Fifty-fourth Street.

THE TREATMENT OF HYPERACIDITY—THE FRENCH VIEWPOINT.

By MARTIN E. REHFUSS, M.D.,
PARIS, FRANCE.

Notwithstanding the enormous amount of clinical material and the abundant clinical observations on the subject of hyperacidity, the precise factors which determine an alteration in gastric secretion are not known. Many concomitant conditions are constantly observed, but the relation between and the mechanism by which they induce these changes are but imperfectly understood. That definite organic conditions such as appendicitis, cholecystitis,

cholelithiasis, and nephrolithiasis can give rise to hyperacidity of the gastric juice must rest unquestioned inasmuch as removal of the cause results in prompt amelioration of all the symptoms and a lowering in the acidity as determined by analyses. That the quality of food and the rapidity of ingestion play an important rôle must be equally acknowledged inasmuch as a sensitive stomach readily reacts to these stimuli. That certain constitutional states such as gout and chlorosis as well as neurosis seem to be factors is the conclusion of men who have had great experience in this condition. The same may be said of the hyperacid states following the excessive ingestion of alcohol and the abuse of tobacco. Finally ulcerative conditions of the gastric mucosa, whether induced by it or inducing it, in turn make it play a very important part in the diagnosis of that condition. Putting aside all these causes, however, there are a certain number of cases in which none of the above named factors seem to operate and there seems to be a disposition on the part of gastric mucosa to react to the slightest stimuli with the formation of hyperacid gastric juice. Some experiments in which I have been recently engaged would seem to show that the stomach has great eliminative powers and in cases of insufficient elimination elsewhere, the stomach can partially assume this function. This is well known in the case of uremia and it is probable that many drugs can also be eliminated in this way. It is possible that during the process of elimination hyperacidity can be induced. Bourget in his "Maladies de l'Estomac," just published, says that the commonest cause of hyperacidity, however, "outside of that attending ulcerations, is certainly a neurosis with, as its habitual complement, spasm of the pylorus." Before leaving the subject of hyperacidity, an important point in the analysis of this condition is the fact that a number of medicinal substances can by prolonged usage produce hyperacidity and principal among these is sodium bicarbonate when used in too strong concentration or when used to excess.

It is therefore interesting in the study of this important condition to study the methods based on the results of an enormous number of cases used in the treatment of this condition in France. By means of the precise methods of chemical examination of the gastric juice following the method of Hayem and Winter, the careful determination of the mechanical function, and the *x*-ray of the stomach by direct vision with the screen as practised by Beclere, Bensaude, and others, gastric conditions have been more sharply differentiated and organic faults separated from those the result of purely functional disturbances.

The question of the diet in this condition is, of course, an important one and the general consensus of opinion leans toward a mixed or lacto-vegetarian diet. The fundamental idea of sedation is generally considered preferable to the use of a nitrogenous diet which although it fixes the excess of acid does not reduce its formation. In the severest cases, an absolute milk diet is enforced, but in the milder grades a lacto-vegetarian diet such as Robin indicates under the treatment of "dyspepsia hypersthenique" is the one adapted. Robin gives for breakfast a cup of extremely weak tea, a slice of well toasted bread and butter, and a compote of stewed fruit. The tea may be replaced by a thin cereal such as oatmeal or rice. To individuals with a large appetite, he permits a soft boiled egg. For lunch and dinner, a choice is made of the following: "bouillon-du-pot-au-feu," which is bouillon prepared from the ordinary ingredients, but allowed to simmer for a long time and to which many vegetables have been added—the whole being well skimmed of fat, in reality a strained vegetable soup prepared slowly. Purées of all the vegetables, prepared with water and a little butter, light fish, salads without dressings, macaroni, and much later chicken and well roasted beef, without juice or sauce. Eggs very moderately, and salt is diminished without being suppressed. As entrements beaten cream or white of egg and as dessert stewed fruit. Little bread is permitted and only when well toasted. As to drinking, he recommends pure water or Evian, or a very feebly alkaline, nongaseous water such as Alet.

In the medical treatment of this condition many methods have been extolled such as almost complete suppression of the salt, or a fatty diet, or the galvanization of the vagus or even internal galvanization of the stomach as well as intragastric sprays, but the method of choice in our present state of knowledge is alkaline medication. Bourget points out the method which nature employs to relieve this affection. He says: "You have remarked, no doubt at times in your own case, after a repast a little more copious than ordinarily that the salivary secretion is slightly exaggerated toward the third or fourth hour of digestion, and you swallow more of that saliva, which, coming from different glands, is alkaline in reaction. It can therefore feebly correct the exaggerated gastric acidity. All hyperchlorhydriacs have unconsciously contracted the habit of stimulating their salivary secretion by a form of suction of which one may readily observe the mechanism. They can therefore extract from their salivary systems a larger quantity of saliva, which they swallow and which gives them temporary relief." He adds: "I have often observed in inveterate hyperchlorhydriacs a distinct hypertrophy of the most prominent salivary glands such as the submaxillary and parotid groups, without doubt an evidence of exaggerated function." He believes that the mucus removed from the stomach by tubage in these cases is salivary in origin.

Robin ("Therapeutique Usuelle du Praticien") in his treatment of "dyspepsia hypersthenique," a condition of which the essential feature is hyperacidity, indicates one method of dealing with these cases. He gives 8 to 12 drops of the following mixture about ten minutes before meals in a little water: equal parts of tincture of belladonna, tincture of hyoscyamus, and tincture of opium. The belladonna, according to Robin is a secretory moderator and with hyoscyamus has a sedative action on the gastric filaments of the vagus. The opium calms the gastric hyperesthesia. The dose seems feeble, but he claims sufficient and without any deleterious action on the stomach. After the meal, to saturate the hyperacidity and to prevent the spasm of the pylorus as well as to inhibit prolonged irritation of the mucosa, he gives the following powder in a little Vichy water: magnesium hydroxide and bicarbonate of soda, of each 8 grams; white sugar and precipitated carbonate of calcium, of each 16 grams; mix and make 24 powders; after each meal take one in a little Vichy. This he calls the powder of "petite saturation," but when severe pains, cramps, and heartburns make themselves apparent, he gives the second powder, which he calls

the "powder of grand saturation," as follows: magnesium hydroxide, 1.60 gram; bicarbonate of soda, 1 gram; white sugar, 2 grams; codeine, 0.01 gram; carbonate of calcium and subnitrate of bismuth, of each 0.80 gram; mix and make one powder. This powder seems to border on polypharmacy, but Robin finds in each ingredient an indication. Magnesium hydroxide saturates the acids of the stomach and forms with them a chlorolactate of magnesium, which stimulates the muscular fibers and in this way gives rise to the normal evacuation of the stomach and intestines. Bicarbonate of soda has the property of combining much more rapidly with the acids than the earthy alkalies and of giving the patient an immediate feeling of relief. Soupalt claims that the relief produced by the ingestion of bicarbonate of soda is not so much due to the neutralization of acid as to the disengagement of carbonic acid gas which is distinctly analgesic. He says this explains the relief of pain seen in cases of hypoacidity, the opposite condition. The carbonate of calcium acts in the same manner as the former in its rôle of antacid, and is without laxative properties. The subnitrate of bismuth protects the mucosa and compensates for the occasional too laxative action of the magnesium. The codeine calms the solar plexus and finally the sugar is added to make the preparation palatable. The different ingredients are altered to suit each case: should there be diarrhea, the magnesium is reduced and the quantity of calcium and bismuth are increased; and in the case of constipation *vice versa*. The above prescriptions are most efficacious and freely used over here. In several clean cut cases of hyperacidity and pylorospasm, the above treatment left nothing to be desired.

Incidentally before leaving Robin's methods, it might be well to give several prescriptions for nausea pain, which is a more or less constant accompaniment, for which he recommends the following: Dionin, 0.20 gram; aq. laurier ceris (cherry laurel water), 10 grams; 6 to 8 drops to be taken with a powder of "grand saturation," or a tablespoonful of the following: Cocaine hydrochloride, and codeine of each 0.05 to 0.10 gram; lime water, 160 grams; and chloroform water, 40 grams. Finally, should this be insufficient, there is administered a teaspoonful of the following: Novocain, 0.05 gram; anesthesin, 0.40 gram; cherry laurel water, 10 grams; and simple syrup, 50 grams.

Bourget ("Maladies de l'Estomac," 1912) treats the hyperacidity in an entirely different way and gives the alkalies in considerable dilution. He advocates the use of sodium bicarbonate because it combines readily with the hydrochloric acid and forms the salt most acceptable to the bodily economy. Bourget insists on the following: (1) Solutions of the alkalies should not be given in concentration exceeding 1:100; (2) the supreme thing to be realized is not a neutralization of the acid, but a diminution to the normal point; (3) the effect of strong concentrations and powders is to stimulate the further production of acid. The following is the formula which he uses: Sodium bicarbonate, 8 grams; sodium phosphate, 4 grams; sodium chloride, 2 grams; and water, 1,000 cubic centimeters. He usually gives a prescription calling for six powders each containing the above quantity of the first three ingredients and to be dissolved in a liter of water. The addition of phosphate of soda, he claims has given him very good results, which he attributes to the exciting influence of that salt on the soluble ferments of the intestinal tract. The sulphate of soda also plays a rôle in intestinal digestion and furnishes the material for the formation of the conjugate sulphates, by which the organism can get rid of indol, skatol, and cresol, formed by intestinal fermentation. The above mixture he gives in doses of 50 to 100 cubic centimeters and if digestion is well supported without any untoward symptoms, he waits until the third or fourth hour for correction. In certain cases, there is an excess of acidity only during certain stages and it is at these times that he corrects it. He varies the proportions of the ingredients occasionally and in cases of high acidity he increases the bicarbonate to 10 grams to the liter, never more. If constipation obtains, he decreases the bicarbonate and increases the sulphate to 45 grams to the liter. He also mentions the use of mineral water in the treatment of this condition such as Vichy and Vals in France, Ems in Germany, Carlsbad and Marienbad in Austria, and Tarasp in Switzerland, though the above formula fulfills all indications.

Binet of Vichy has investigated the question of the action of sodium bicarbonate and discusses its action. Hayem accuses sodium bicarbonate of augmenting hyperacidity by excitation and also augmenting hypoacidity by draining the glandular secretions and eventually causing a gastritis. This is true after large doses or too long continued administration. Enriquez and Amba know the utility of the alkalies, but they do not consider them as medicaments capable of producing chloridization of the organism and of acting indirectly as agents producing hyperacidity of the gastric juice secreted. Binet from the result of his work comes to the conclusion that bicarbonate of soda is a substance inoffensive and invaluable in the treatment of dyspepsias providing that it does not exceed 4 to 5 grams a day, taken in 4 or 5 doses and on condition that it be combined with an appropriate dietetic régime especially suited to each case.

Fleiner in 1893, following the indication of Kussmaul, practised "pansement" of ulcer of the stomach by the use of large doses of bismuth subnitrate administered through the stomach tube. This method has been vulgarized in France by Hayem, Lion, and Mathieu. M. Agasse Lafonte, who was Hayem's chief of clinic for many years, tells me that Hayem in treating hyperacidity simply makes use of large doses of subnitrate of bismuth. He considers the other methods inefficient inasmuch as they merely relieve and do not cure. Furthermore, he claims, as stated above, that bicarbonate of soda augments the condition and begins his treatment by interdicting all medication, especially bicarbonate of soda and chloroform water. Hayem claims that subnitrate of bismuth is above all the medicament for pain as well as spasm. Especially in ulcer it causes a disappearance of pylorospasm which is one of the most fruitful causes of evil. Monneret considers it of use in hemorrhage and Lion and Ruault believe that it inhibits abnormal fermentation. Analyses have determined that there is a rapid reduction of acidity in the presence of bismuth and nearly all the chlorine is fixed on the bismuth in the form of an isoluble oxychloride. In the administration of bismuth Hayem orders in the morning 20 to 30 grams of subnitrate in a glass of water with several teaspoonfuls of syrup of acacia. The patient is put at the same time on a lactovegetarian diet and this treatment is kept up for 10 to 20 days. After 4 to

5 days of treatment distinct improvement is noticeable. The effect of the bismuth is to form a "pansement" or protecting layer and to excite the formation of a small layer of mucus, which aids in the result to be attained. Two objections apparently present themselves to this method, both of which seem to be without foundation. First, it would be supposed that such large doses of bismuth would absolutely lock up the bowels. The reverse is true and practical experience seems to show that large doses are actually laxative in action and that it is occasionally necessary to reduce the dose owing to diarrhea. Secondly, it will be urged that bismuth is toxic, especially the subnitrate. This was studied by Bensaude and Agasse Lafonte, especially with reference to accidents connected with .r-ray work, and the conclusions which they draw are that the subnitrate only constitutes a danger when the medium in which it can act is alkaline, and in cases in which there are signs of actual obstruction. In the presence of these two factors through the action of certain bacteria the nitrates are changed into nitrites and the individual is intoxicated. This of course does not obtain in hyperacidity, where the medium is acid and clinical experience demonstrates that it is absolutely harmless. One individual has taken as much as three kilograms of bismuth subnitrate or 20 grams each on 155 successive days without any toxic symptoms. If pure bismuth is used the fear of intoxication by lead, antimony, or arsenic need not be feared.

It will be evident that each method has arguments in its favor and that each case must be a law unto itself. In ulcer without doubt the bismuth treatment is the best and has received the support of the majority of physicians. In hyperacidity accompanied by severe pain of short duration it is probable that the method of Robin offers the most satisfactory solution, while in the type of mild hyperacidity, with heartburn and pain lasting over several hours, the prescription of Bourget given in repeated small doses is best. Finally, in the mildest cases the simplest of the feebly alkaline nongaseous mineral waters might be appropriately administered.

American Hospital.

ENLARGEMENT OF MEDIASTINAL GLANDS.*

By GUSTAV F. BOEHME, Jr., M.D.,

NEW YORK.

ASSISTANT PHYSICIAN BELLEVUE HOSPITAL OUT-PATIENT DEPARTMENT; CLINICAL ASSISTANT, DEPARTMENT OF INTERNAL MEDICINE, ST. BARTHOLOMEW'S CLINIC.

The study of a case of mediastinal gland enlargement due to syphilis led to the rather careful investigation of this field, and this paper is presented as a review of the subject matter found. No originality is claimed, yet so little time is given to the diagnosis of these conditions that we feel justified in here presenting a résumé of the clinical picture of mediastinal glandular involvement.

The anatomy of the region is doubtlessly clear, the mediastinum consisting of two portions, the upper of which lies above the upper limit of the pericardium and the lower beneath it. The latter is again divided into three portions, the anterior, middle, and posterior mediastina lying relatively in front of, including, and behind, the heart. The superior mediastinum contains the arch of the aorta, the innominate artery, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior vena cava and the innominate veins; the trachea, esophagus, and the thoracic duct; remnants of the thymus gland and lymphatic glands; and the pneumogastric and left recurrent laryngeal nerves. The anterior mediastinum contains loose areolar tissue, lymphatic vessels from the liver, the anterior mediastinal glands and small mediastinal branches of the internal mammary artery. The middle mediastinum contains the heart, aorta, lower half of the superior vena cava with the vena azygos major; the bifurcation of the trachea and two bronchi, the pulmonary artery dividing into two branches; the right and left pulmonary veins, the bronchial glands, and the phrenic nerves. The posterior mediastinum contains the descending thoracic aorta, the greater and lesser azygos veins, the pneumogastric and sympathetic nerves; the esophagus, the thoracic duct, and the lymphatic glands. It will therefore be plainly evident that enlargement of any kind in these regions will press upon important structures and by this pressure cause definite symptoms. As we are particularly interested in the glandular involvement a study of these glands will be necessary.

The thoracic glands may for convenience be divided into three groups: (1) the anterior mediastinal nodes, five or six in number which lie in front of the transverse arch of the aorta. (2) The posterior mediastinal nodes which surround the esophagus, but are more numerous in front of it. (3) The peritracheobronchial nodes which are divided according to Barety into four groups: (a) the group to the right of the trachea extending from the right bronchus upward to the region of the subclavian vessels; (b) the group to the left of the trachea ascending from the left bronchus to about the arch of the aorta and the recurrent laryngeal nerve; (c) a group about and below the bifurcation of the trachea, commonly known as the bronchial glands; (d) the interbronchial nodes lying in the angles of the bifurcation of the large bronchi.

In his monograph, "Tuberculosis of the Bronchial Lymph Nodes," Professor Schlossman of Düsseldorf divides them into the tracheobronchial nodes, the bronchial nodes, and the pulmonary nodes. He further declares that "their enlargement leads most especially to pressure upon the trachea, the larger and middle sized bronchi, as well as upon the recurrent laryngeal nerve." According to Friedleben the nodes "lying below the concavity of the right subclavian are frequently affected, especially in tuberculosis." The lymph enters these glands from the anterior portion of the diaphragm, from the upper surface of the liver, from the pericardium, and from the thymus. The posterior mediastinal glands receive lymph from the esophagus, the posterior part of the diaphragm, the pericardium, and the liver.

History.—The first time mediastinal disease was mentioned was by Thomas Wells in 1670. In 1742 a steatoma of the anterior mediastinum was recorded by H. Boerhaave. Lieutaud, between 1703 and 1780, reported several cases of mediastinal disease. The first textbook description was that by G. C. F. M. Lobenstein in 1835. Since that time numerous articles have appeared, among which the study of some 520 cases by Professor H. A. Hare in 1889 and the article of Pepper and Stengel on

*Read at a meeting of the Tri-Professional Society, March, 1912.

mediastinal tumors are probably of classic interest.

Varieties of Mediastinal Lymphatic Gland Enlargement.—(1) Acute lymphadenitis: (a) hyperplastic; (b) exudative or suppurative. (2) Chronic lymphadenitis. (3) Tuberculosis of glands. (4) Syphilitic envolvement in (a) secondary stage; (b) tertiary stage (gumma). (5) Hyperplasia (lymphoma: (a) leucemic; (b) pseudoleucemic (Hodgkin's disease). (6) Tumors: (a) sarcoma, (b) fibroma, (c) myxoma, (d) chondroma, (e) endothelioma, and (f) carcinoma.

Etiology and Pathology.—Acute lymphadenitis of the hyperplastic type follows diphtheria, scarlet fever, typhoid fever, and the bronchitis of measles. It is also present in pertussis as a fairly constant symptom and, because of pressure effects, according to de Mussy, is responsible for the paroxysms of whooping cough. Pathologically the picture is one of hyperemia and hemorrhage in the lymph nodes with a proliferation of the mononuclear elements. Necrosis of the hyperplastic tissue occurs in some instances, *e.g.* in typhoid fever, diphtheria, or scarlet fever. Generally resolution occurs, or if necrosis occurs, fibrosis may fill in the area, or suppuration ensues. Acute lymphadenitis of the exudative or suppurative type occurs as a rare sequence of the acute hyperplastic type, in pyemia, and septicemia or secondary to a tuberculous process. The picture is one of a suppurative inflammation anywhere. In the type following secondary infection of the tuberculous glands grave complications may ensue. Rupture into the esophagus, the bronchi, and the aorta have been described. Sidney Phillips described a case in which the gland had ruptured into the aorta and a bronchus at the same time, giving rise to attacks of hemoptysis for a considerable period of time. Chronic lymphadenitis occurs as a result of frequent moderate degrees of inflammation and as a result of the constant inhalation of dust. This latter type is met with chiefly in pneumokoniosis. Two pathological types exist: (1) The type in which the fibrous tissue is markedly increased due to constant irritation or (2) the type in which the cellular elements are increased in number and the glands are much enlarged.

The enlargement of the mediastinal glands due to tuberculosis and its relation to pulmonary tuberculosis is a subject which in itself requires more study. It will suffice to state that up to the present time various modes of infection by the tubercle have been described. The avenues of infection are numerous and of these the following are suggested: (1) Following cervical tubercular adenitis. Here, however, we would suggest that such path of infection is not proven. Recent experiments in which the cervical lymph glands were injected with a colored fluid show no connection between the cervical and the bronchial glands. (2) Following pulmonary tuberculosis. The lymphatics of the lungs all drain into these glands and secondary infection occurs here. It is extremely easy to come to the conclusion that such glands caused the pulmonary tuberculosis when as a matter of fact a low grade pulmonary tuberculosis has been responsible for their enlargement. (3) Hematogenous infection. The lymphatics are in direct communication with the blood and tubercle bacilli in the circulation may readily find lodgment within them. Of the three possible modes of involvement the latter two seem the more logical.

Syphilitic involvement of the mediastinal glands may be of two types; that occurring in the general lymphatic enlargement accompanying the second stage of this disease, or the tertiary involvement by gumma. Of the two, the latter is the type most commonly described. The pathological changes in the glands are those of similar syphilitic processes elsewhere and do not need description here.

An interesting variety of mediastinal lymph gland involvement is that known pathologically as lymphoma or hyperplasia of the lymphatic glandular structure. This is of two types: (1) Leucemic lymphomata accompanying lymphatic leucemia or (2) the pseudoleucemic lymphomata occurring in Hodgkin's disease. The latter type is usually primary, the former more often secondary to other lymphatic enlargements due to the disease.

Of the tumors of the mediastinal lymphatic glands the most common, according to Hare's figures, are the carcinomata They may be primary, but more often are secondary to tumors elsewhere. Such secondary involvement may follow a number of avenues. It may enter through the chest wall from the breast through the lymphatics draining into the chain of glands following along the line of the internal mammary arteries. Again it may be carried by vascular embolism from an external focus. The disease may spread from abdominal organs to the under surface of the diaphragm, and may penetrate it by way of the lymphatics and thus reach the glands of the chest. Or embolism may "occur through the thoracic duct to the chest and then by retrograde metastasis to the mediastinal glands," as described by Tyson. Sarcomata may be primary or secondary and are not uncommon. They are often, when primary, mistaken for aneurysm of the aorta. All types of the tumor may be presented. Numerous other tumors have been described. Most are secondary; some, however, as the fibroma and myxoma, may be primary. Chondroma and epithelioma are usually secondary.

Symptomatology: The symptoms due to the enlargement of the mediastinal lymph nodes are manifold and present a bizarre picture. Oftentimes the condition may be entirely latent and is only recognized at autopsy. This is plainly shown by the report of the result of 7,566 autopsies at the Marine Hospital at Cronstadt, among which 158 malignant mediastinal tumors were found. The condition is suspected in so few instances, and may, as in the case to be described, be so masked by other more evident signs that it may be entirely overlooked unless careful routine physical examination is undertaken. The disease can readily be divided into two types: (1) Mediastinal glandular enlargement occasioning chiefly physical signs, and (2) mediastinal glandular enlargement occasioning symptoms and but few physical signs. The first type is more often met with in involvement of the anterior mediastinal nodes; the latter, in enlargement of the middle and posterior mediastinal nodes. As the pathological and anatomical distribution of the glands varies the clinical picture so much we shall here attempt to classify the semeiology and symptomatology according to such arrangement.

I. Lymphatic enlargement in the anterior mediastinum. This is more often only discovered on careful routine physical examination. Symptoms develop only with considerable enlargement of these glands. They may be summarized as follows: (1) Marked prominence and distention of the veins of the upper part of the body. This is usually accompanied by coldness of the upper extremities, cya-

nosis and edema. If the disease is of long standing, clubbing of the fingers occurs. These symptoms are explained by the pressure of the enlarged glands on the superior vena cava and the right and left innominate veins, damming back the blood into the upper extremities and the head. (2) Inequality of the radial pulses may appear due to pressure upon the arteries, chiefly the subclavian. The tumor may thus be mistaken for aortic aneurysm. (3) Hoarseness and even aphonia occurs in the majority of cases occasioned by pressure upon the recurrent laryngeal nerves. The left nerve is more often pressed upon because anatomically it circles below the aortic arch in close proximity to the greater number of mediastinal glands. (4) Inequality of the pupils may occur, due to pressure on the sympathetic nerves. (5) Unilateral flushing of the face sometimes is present, due to a similar cause. (6) The pulse varies. It may be exceedingly slow because of pressure on the pneumogastric nerve or it may be very rapid because of involvement of the sympathetic nerves, or the pulse may be very irregular due to both causes. (7) Cachexia may be present. This is preeminently the mediastinal lymphatic gland involvement of physical signs. Usually they do not appear until the involvement is very extensive, hence may often be missed. The signs so far described are somewhat as follows: (1) Bulging of the sternum with, in some cases, erosion of the bone itself. (2) Displacement of the apex-beat usually downward and to the left. (3) Pulsation may be present. It is synchronous usually with the systole of the heart, but it is not expansile, differentiating it from the impulse of aortic aneurysm. (4) Tactile fremitus may be increased or diminished depending entirely on the location of the tumor and its relation to the lung. (5) An abnormal area of dullness may be mapped out, in some instances, of irregular shape just above the upper cardiac limit. (6) Auscultation is usually negative. In some instances, however, there may be changes in vocal fremitus, which may be increased or diminished, depending on the locality of the glandular enlargement and its relation to the lung. A systolic bruit can sometimes be elicited which is probably due to pressure of the mass on the aorta or pulmonary artery. (7) In some instances signs of hydropericardium or hydrothorax may be present. These conditions are due to pressure on the great vessels damming back the blood and thus interfering with circulation.

Lymphatic enlargements in the middle and posterior mediastinal spaces. These may be entirely latent and are often found only at autopsy, especially those of the tubercular variety. The acute lymphadenitis is extremely difficult of diagnosis, although according to de Mussey, an area of dullness over the upper part of the interscapular region and dorsal vertebræ, as far down as the fourth, is diagnostic of posterior mediastinal lymphatic enlargement and is constant in pertussis. Such views, however, are not held by many able clinicians. The suppurative adenitis is often missed and it should not be forgotten (and here I quote Butler) that "a single profuse expectoration of pus during the course of pulmonary tuberculosis may be due to the rupture of a gland into the lung." The septic type of temperature with a leucocytosis should not be forgotten as a clinical indication of a suppurative process. In general, glandular involvement of these regions present few, if any, physical signs and the diagnosis is made by the symptomatology. The chief symptoms follow: (1) Dyspnea usually of an inspiratory type is due to pressure on the trachea or bronchi, or pressure on the recurrent laryngeal or vagus nerves. (2) Cough, which is often paroxysmal and whooping in character. It is attributed to the joint involvement of one vagus and pulmonary plexus. (3) Dysphagia due to pressure on the esophagus. (4) The pulse varies in a similar manner to the variations in anterior mediastinal involvement. (5) Vomiting occurs and is said to be due to vagal irritation transmitted reflexly to the stomach. (6) Edema of the upper part of the abdomen and serous effusion into the chest may be present and are caused by pressure on the venæ azygos. Direct pressure on the vena cava inferior may cause ascites and hepatic congestion. (7) Syncope is not unusual and is attributed to pressure on the vagus. (8) Fever is moderate or may be entirely absent. (9) Cachexia is far more frequent in this type of involvement than in anterior mediastinal gland enlargement. The physical signs of this condition are slight and are those previously described under acute lymphadenitis: an area of dullness in the interscapular region extending downward to the fourth dorsal vertebra.

Diagnosis.—The presence of mediastinal lymphatic enlargement is usually missed unless the clinician is particularly interested in this field of physical examination. The type of enlargement must be determined by the history of the case, the blood picture in the leucemic enlargement and in Hodgkin's disease, and the serum reactions in syphilitic growths. Sometimes external foci may assist in clearing the diagnosis. Sputum examination and tuberculin reactions point to tuberculous involvement. The differential diagnosis from aneurysm of the aorta, pericarditis with effusion, and pleurisy with effusion must be made. From aneurysm of the aorta the diagnosis is made by the history of the case, the diastolic shock, the tracheal tugging, and the expansile pulsating tumor which is present in that condition and not in mediastinal lymph gland involvement. Careful analysis of the physical signs will readily differentiate pericarditis and pleurisy with effusion. Tumors of the thymus, pleural tumors especially endotheliomata, and other similar growths within the mediastinum must be differentiated by the particular physical signs of each case and the clinical sense of the observer. The *x*-ray is often of material assistance in outlining the tumor.

Treatment.—The treatment varies with the causative factor and as a general rule is very unsatisfactory. If there is a simple adenitis due to pertussis, one of the exanthemata or a bronchitis, expectancy so far as the local process in the glands is concerned, is the practice with the proper therapy of the underlying cause. If suppurative adenitis is suspected, aspiration may be tried with caution, followed if necessary by operative procedures. The general treatment can be outlined as follows: A. Medical: (1) Treat the cause: *e. g.* the use of mercury and the iodides in syphilitic processes; arsenic in sarcoma, Hodgkin's disease and leucemia. (2) Supportive: Proper diet and stimulation. (3) Symptomatic: Meet pressure symptoms and signs of other involvements as occasion may arise. Cough and dyspnea, the most urgent symptoms usually, are met medically with narcotics and inhalations of oxygen. B. Surgical: (1) Intubation or tracheotomy if urgent dyspnea is present, or intratracheal insufflation may be tried. (2) Opening into the

thorax under negative pressure (Sauerbruch apparatus) or positive intrapulmonary pressure (diver's helmet with compressed air). Walker of Detroit has successfully operated on a large fibrosarcoma of the anterior mediastinum. (3) The *x*-rays may be used in Hodgkin's disease and leucemic enlargements. Combined with Coley's mixed toxins the *x*-rays are said to have caused the subsidence of sarcoma and lymphosarcoma.

Case I.—J. R. Born in the United States. Family history negative. Previous history: Went to school from his fifth to his fifteenth year. He then worked as an order boy to his nineteenth year when he entered the United States navy. With Admiral Dewey he went to Manila and took part in that battle. He remained in the Philippines, undermining his health by all excesses. Then he returned to the United States and joined the Jersey City police force, serving for six years, and was finally forced to leave the service. He then knocked around the country as a hobo and finally returned to Jersey City. Habits: Sleeps poorly because of dyspnea. Appetite good; bowels regular. As long as he can remember his bladder control has been poor, at times being incontinent. Has a sharp pain whenever he urinates. His urine has never been smoky or cloudy. The quantity voided daily has increased; has to get up a half-dozen times a night to urinate; his first attempt at micturition results in a few drops being passed; later the stream becomes powerful. Alcoholic: Has always been a heavy drinker, taking as many as twelve glasses of whiskey daily. Coffee: Drank as many as half-a-dozen cups of coffee at one meal. Loss of weight: He declares that he has lost 50 pounds in the two months preceding this history. Has had marked night sweats. Venereal: Has had gonorrhea about a dozen times. So far as he knows he has never had a stricture nor have any sounds been passed. Ten years before the present trouble he had a chancre, followed by an eruption over the entire body, a sore throat and later leg ulcers. He never underwent any medical treatment for his venereal disorders.

Previous medical history: As a child he had measles, scarlet fever and pertussis. Appendicitis when 23 years old. Still later had half-a-dozen epileptic attacks of alcoholic origin. Yellow fever and malaria when in the Philippines. Previous surgical history: While in the Philippines was struck on the head by a bolo and lay unconscious for two days. Present illness: One year ago while in Florida he noticed a shortness of breath especially when lying down at night. While erect the dyspnea ceased. He began to cough and brought up a considerable amount of white sputum which later became blood tinged. After six months he came North and spent his summer in northern New York. His condition grew progressively worse until the shortness of breath continued day and night, and the patient entered the Utica City Hospital where he was treated for nine days for asthma with potassium iodide, under which treatment he improved. He then came to Jersey City, where he received medical treatment from various physicians. He finally entered the City Hospital complaining of shortness of breath night and day, and huskiness of voice. He also suffered from a cold with cough, which was productive of a white sputum, very scanty in amount. Physical examination: Height, 5 feet 9 inches; weight, 142 pounds. Temperature, 100.4°; pulse, 80; respiration, 24. The patient was poorly nourished, and his muscles were flabby. Mucous membranes anemic. Body showed numerous symmetrically distributed brown spots. Legs show old scars from ulcers. The patient feels weak and has a slight degree of vertigo. The eyes show a slight degree of inequality of pupils, otherwise are normal. Hearing is normal. Cutaneous sensibility is normal. No Romberg. Speech: Voice is extremely husky, sometimes descending to a whisper. Thorax: Chest is well developed; broadened in the anteroposterior diameter. Sternum convexly curved. No visible pulsations or tumors. An area of increased tactile fremitus over the left side anteriorly from apex to fourth rib and to the fifth rib posteriorly. No abnormal pulsations palpable. An area of dullness from the apex to the fourth rib on the left side anteriorly and to the sixth rib posteriorly can be mapped out. A second distinct area of dullness can be mapped out as follows: Upper border, ¼ inch below suprasternal notch; to right, 3 inches from median line irregularity; to left, 2½ inches from median line; below melts into upper cardiac dullness. Over the area of dullness on the left side bronchial breathing with moist râles. Over the area of dullness in the median line the breath sounds were obscured. No bruit could be made out. Heart normal. Abdominal: No abnormalities. Rectal examination showed an enlarged prostate. In the physical signs attention is directed to an area of dullness just above the heart.

Clinical pathological findings: The urine showed the picture of chronic parenchymatous nephritis. Blood: Red cells, 4,608,000; leucocytes, 16,000; hemoglobin, 90 per cent. Differential: Polynuclears, 78.6 per cent.; lymphocytes, 19.2 per cent.; eosinophiles, 1.4 per cent.; transitionals, .5 per cent.; mast cells, .3 per cent.; Noguchi test, positive. Sputum showed tubercle bacilli. The diagnosis made at this time was (1) chronic pulmonary tuberculosis; (2) chronic parenchymatous nephritis; (3) mediastinal tumor, probably of syphilitic origin. Potassium iodide was prescribed in increasing doses, but the next day the dyspnea grew worse and the voice more brassy. On December 15 the patient was seen by Dr. Bull, who diagnosed the condition as one of paralysis of the vocal cords due to recurrent laryngeal nerve involvement and the patient was intubated. Injection of mercury salicylate in alboline were then advised, under which treatment the patient improved, the tube being removed. The voice became clear and the dyspnea nearly disappeared. The patient, who was rather querulous and of a combative disposition, then refused further injections and his condition grew worse. Mercury protoiodide was then resorted to in doses of 1/6 grain t. i. d., and the patient again cleared up nicely. Finally on February 9 he went home much improved. On his discharge from the hospital the area of dullness in the median line had nearly disappeared, and only a small area posterior to the sternum showed any dullness.

This case then presents, besides the chronic conditions, a clinical symptom-complex as follows: A history of syphilis, a positive Noguchi test, a hoarse voice, dyspnea, paralysis of vocal cords, an area of dullness just above the cardiac area, inequality of the pupils, and reaction to specific treatment. The whole picture would seem to indicate a mass pressing upon the recurrent laryngeal nerves occasioning the pressure symptoms noted. As aneurysm of

the aorta can be ruled out, the most logical conclusion seemed to be enlargement of the middle and anterior groups of the mediastinal glands due to syphilis.

A PLEA FOR A MORE CAREFUL EXAMINATION IN DERMATOLOGY.

By BENJ. F. OCHS, M.D.,

ADJUNCT ATTENDING DERMATOLOGIST TO THE LEBANON HOSPITAL AND DERMATOLOGIST TO THE HARLEM HOSPITAL, O.P.D.

While as a rule dispensary practice is a routine one and time does not allow a thorough examination of patients, nor are the accommodations sufficient for good and thorough work, yet when one gives a little additional time to the work, not only do the patients seem more grateful to the attending physician, but the doctor sees many a case which in the rush of time he would ordinarily overlook.

It has been our invariable rule, that every case that presents itself for the first time shall be thoroughly examined, and that, in dermatology, means that they should be entirely exposed. This rule, with us, is an inflexible one. No matter whether the patient comes for a lesion on the scalp or an apparent impetigo, confined to the face. In this way we have seen quite a few interesting dermatological cases, which ordinarily we would have overlooked. Thus, in examining a child for a ringworm of the arm, we also found, upon exposure, a typical lichen planus. At another time, a woman who came for an alopecia areata was found to have a gumma of the back. A young man with a barber's itch was found to have psoriasis. These and many more such instances have led us to establish the rule *always* to expose our patients, at least once, and that upon their first visit. How often a case of scabies of the most typical kind is treated only as such, when as we have seen in our service at both Lebanon and Harlem Hospital dispensaries, they are suffering from a mixed infection. We have seen scabies, combined with a maculopapular syphilid, with acne and even with lichen planus; and only a careful examination of the whole body would reveal such dual diseases.

Ofttimes an examination of the rectum will show condylomata, while careful examination of the mouth reveals mucous patches or aphthous conditions. The trouble of a thorough examination of the body is that it takes up a whole lot of time and that we meet with the refusal of patients, who do not see the necessity of such and cannot see the value of an exposure when their lesions are confined, as they believe, to the face, arms, or legs. Again, when the body is exposed to the dermatologist, he can see not only the lesion for which the patient came, but also follow the course of the disease; he will frequently be able to see beginning lesions in one part of the body—retrogressing in another part, as well as the lesion at its height, and thus have a clearer conception of the disease. Take, for instance, a case of scabies: the patient presents only his hands for inspection, but upon examination he will show lesions on his buttocks, genitals, etc., though the diagnosis may easily be established from his hands only.

A case of chromophytosis of the chest may show similar lesions on the back and will frequently show similar patches on the mons veneris. Lichen planus on the trunk may show lesions in the mouth as well as on the genitals.

So we must not be too lenient in our examinations and take for granted the statement of the patient that the body is free, but examine each case closely. And what holds good for dispensary work surely holds good for private practice. The patient feels indignant if his word is doubted that there may be lesions on any other part of the body excepting that which is presented for examination. Here, again, frequently mixed infections are found. Therefore, it is advisable always to examine the whole body and this is done to the best advantage if there is a complete exposure to the physician. Both physician and patient can but profit by such examination, and in conclusion I would recommend: *Examine your patient from head to foot.*

1990 Seventh Avenue.

A Tracheotomy Tube Worn for Fifty Years.—St. C. Thomson has recently demonstrated a tracheotomy tube which had been worn by one patient, on and off, for sixteen years. Frequently the tube was not changed more than once in two years. Altogether the patient had worn a tracheotomy tube for over fifty years. The patient did not suffer from bronchitis more than other people, and she died of senile decay at the age of eighty-one. While all are agreed as to the value of nasal respiration, this case shows that Nature is full of wonderful compensations, and that in certain cases of laryngeal stenosis it may be wiser to put up with a tracheotomy tube than risk uncertain operations with the object of being able to do without a cannula.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

New York, September 7, 1912.

TUBERCULOSIS AND SUPRARENAL INSUFFICIENCY.

A PERSISTENT arterial hypotension is now regarded as one of the earliest signs of pulmonary tuberculosis. The causation of this manifestation is still veiled in obscurity. There is reason to believe that the diminished blood pressure is in some way associated with a diminished function of the suprarenals. An article dealing with various phases of this subject is presented by Emile Sergent in the *Gazette des Hôpitaux*, July 11, 1912. This observer calls attention to the fact that there are two forms of suprarenal insufficiency occurring in tuberculous subjects. In the first of these the tuberculous lesion is confined to the suprarenal capsules. In the second form there develops in the course of pulmonary tuberculosis a group of symptoms which reveals more or less completely a state of suprarenal insufficiency. The first type may present the well-marked clinical picture of Addison's disease, melanoderma, asthenia, anemia, progressive emaciation, constipation, pains radiating from the lumbar region into the abdomen, vascular hypotension, collapse, and the "white line." According to Dieulafoy and Bressy there are abortive forms of this disease, whose essential characteristic is the absence of melanoderma. But the evolution of the remaining symptoms is more rapid than in the classical type of Addison's disease, for the destructive lesion of the suprarenal capsules is greater. The development of suprarenal insufficiency in individuals presenting marked signs of pulmonary tuberculosis may reveal itself in various ways. Small areas of pigmentation may appear on the skin. This pigmentation is not the same as that characteristic of Addison's disease, in which the cutaneous discoloration grows progressively worse. The disseminated pigmentary patches of tuberculous subjects have a *café au lait* appearance. Boinet has termed this phenomenon "addisonism."

The presence of hypotension in an individual known to have or suspected of having pulmonary tuberculosis, particularly if this symptom is associated with a degree of asthenia, fatigue, anemia, and emaciation out of all proportion to the pathological process in the lungs, is strongly indicative of the presence of suprarenal insufficiency. Many patients presenting this combination of symptoms die with all the signs of acute failure of the suprarenal function, and at autopsy there may be revealed a marked sclerosis of this organ.

Sergent accepts the theory advanced in this country by Russell that a calcium starvation lies at the basis of tuberculosis, and cites the recent experiments of Carnot and Slodu, who have shown that the administration to an animal of suprarenal extract favors the deposition of calcium at the site of fractures. It is suggested also that the reason why tuberculosis is aggravated by gestation is that the latter condition is frequently associated with suprarenal insufficiency. On the basis of these observations Sergent concludes that suprarenal failure plays an important rôle in the evolution of tuberculosis. He advocates a suprarenal therapy in this disease as a means of meeting three indications: (1) The signs of suprarenal insufficiency are frequently manifest. (2) Suprarenal extract combats the tendency to collapse and sudden death. The existence of hemoptysis is, however, a contraindication to the use of this substance. (3) Adrenalin aids in the process of recalcification and tends to counteract thereby the evolution of the tuberculous lesions.

SELF-MURDER.

PROFESSOR BAILEY of the Social Science Department of Yale University gives the three most potent safeguards against human self-murder as the love of life, the sense of duty, the religious fear of punishment after death. Standards as to conduct change from age to age. Among the ancients suicide was considered an act of courage; we of to-day consider it cowardly. And yet such men as Washington, Bismarck, Napoleon, and Lincoln are said, on one or more occasions of dreadful stress in their lives, to have contemplated self-destruction. Suicide seems consonant with Oriental fatalism. The British have had no little difficulty in banishing suttee and like practices from India. The Chinese are said to regard suicide as a religious virtue, which brings them at once to the household of Paradise. The Japanese practice of hara-kiri (now obsolete, or fast becoming so, let us hope) has been or is essentially a heroic act.

Prof. Bailey has noted that males commit suicide more frequently than do females, in the proportion of three and one-half to one; between thirty and forty is the popular suicide age; there are more suicides among married men than among single men. The maximum suicide age is between 20 and 30 for single men; between 30 and 40 for married men; among widowers as also among divorced persons it is between 60 and 70. In America despondency leads as a cause of suicide; and among us shooting is the most frequent means of self-destruction, poison being second. The young favor poison; the middle aged shooting; the old hanging. Women take to drowning, gas, and poison; they avoid injuring their features. In cities suicides jump from buildings or bridges, poison themselves, or turn on the gas; in our Southern States shooting is preferred. Hanging is more popular in Northern Europe; drowning in Southern Europe.

Before comparing these data of Bailey with cer-

tain of Dr. Hoffman, presently to be submitted, we would note that there are epidemics, if not of suicide, at least of the mode or manner of self-destruction. A lay press account, for example, of suicide by shooting oneself in the roof of the mouth will very likely be followed by several cases of the same mode; read of a man who had settled himself comfortably in an armchair, had enveloped himself in a bed blanket, and had beneath this so manipulated a revolver that its bullet entered the heart, and one is likely to see very much the same thing described on several days following. One suicide by the horribly painful method of drinking carbolic acid is sure to be the first of a series of such deaths. Emerson in one of his Essays anticipated Bailey's observation that women suicides avoid injuring their features. Women would commit suicide a great deal more frequently, suggests Emerson, if they could be sure their persons would be romantically attractive after death; none among them would care to be "a demned, moist, unpleasant body," as Mr. Mantilini periodically threatened to become.

It has been noted that women commit suicide less frequently than do men; this is probably, not that they are not as much tempted to do so, but because of their more religious natures. The will-to-live militates against self-destruction; this fundamental force denotes not only resistance to annihilation but also dread of and respect for that power which can both destroy life and preserve it as well: the horror of death and of the factors tending to it, and the passionate desire for life and fear of the power which gave it.

Dr. Frederick L. Hoffman presents in *The Spectator,* a journal devoted to life insurance (July 11, 1912) records manifesting that for the first time in the history of small American cities (under 250,000 population) the suicide rate in them in 1911 exceeded the rate for the cities over 250,000 in population. Among the 100 cities tabulated 79 were in the former class; 21 in the latter (over 250,000). In the 79 cities 1,395 persons slew themselves in 1911; had the ratio of the previous decade beeen maintained there would have been but 957. Moreover, the rate of suicide in the 100 cities tabulated has progressed from 12.8 per 100,000 twenty years ago to 20.30 in the five years period ended with 1911. Why there is this remarkable increase in the small cities Dr. Hoffman does not essay to explain, but he considers that these data furnish "additional proof that the increase of self-murder is real, and that the subject demands the most serious attention"—as it unquestionably does.

From a tabulation of Prussian suicide statistics Hoffman finds the rate of male suicides to have been 32 per 100,000, the female being 10. The suicide mortality under 15 is 0.68, jumping immediately to 16.61 between 15 and 19 years, and to 26.84 between 20 and 24 (at which latter period defective education, mental, moral, and economic is the responsible factor). From 40 to 79 years the rates mount from 34.89 to 58.71; in those years the mentally depressed brood over physical and mental decadence. Mental unsoundness and nervous disease, then alcoholism, then sorrow and distress, are in order the chief causes tending to suicide. Dr. Hoffman concludes that suicide is a real evil of nation-wide extent; and that people contemplating suicide are on the increase in the United States under the complex conditions of American life. "It is equally safe to assume that in quite a number of cases the method of suicide is so ingenious as to preclude an accurate diagnosis. Modern education is largely responsible for social and moral discontent. The considerable amount of publicity which is given to suicides in newspapers, and to the means by which life is voluntarily brought to an end, implies a more serious menace to the community on the well-established basis of the psychology of suggestion."

THE GLANDULAR DISEASES OF CHILDREN.

The large rôle played by the glandular system in the pathology of early life is emphasized by D. Ssokolow in an important article on this subject in the *Archiv für Kinderheilkunde,* June 13, 1912. Glandular diseases, and chiefly those of the lymph glands, constitute one of the most common forms of the diseases of children. The peripheral lymph nodes, particularly those of the submaxillary and cervical regions, are the most vulnerable. Less frequently involved are the deeper lymph nodes, of which the mediastinal and tracheobronchial groups occupy the foreground. Next in order of involvement come the lymph nodes of the abdomen. Affections of any of these glands may run an acute, a subacute, or a chronic course. The etiological factor in any case may be of either bacterial or non-bacterial nature. The most common factor is the tubercle bacillus. Other common causes are the streptococcus, staphylococcus, pneumococcus, influenza bacillus, the microorganism of pertussis, and the colon and typhoid bacilli, the last two affecting chiefly the mesenteric lymph nodes. The diagnosis of disease of the peripheral lymph nodes is not difficult, for in addition to the rise of temperature there are the localized swelling and tenderness. The case is different with the lymph glands situated in the body cavities, for apart from the increased temperature there may be no objective data. The course of the temperature may be a short one with frequent sharp but fluctuating ascents, or it may be prolonged over a period of months or even years, in which case the temperature elevation is not considerable.

Ssokolow emphasizes the necessity of a strictly conservative treatment in all cases of glandular disease. Inunctions, and the practice of massage, as well as other local measures to favor resorption, are to be avoided. Likewise extirpation and premature incision before the completion of suppuration are not favored. A valuable measure in the case of accessible glands is the use of heat in the form of poultices, cataplasms, and light therapy. In the case of diseases of the tracheobronchial lymph nodes it is necessary to send the child to a climate whose atmosphere is free from dust and preferably cold. The treatment of disease of the mesenteric lymph nodes requires a non-stimulating, non-fermentative, and relatively sterile diet.

The Fordham International Extension Course.

An interesting innovation in medical teaching is to be tried this month at the Fordham University Medical School in this city. Hitherto the young graduate, and the older one too, who wished to broaden his medical horizon and to learn at first hand what Europe had to teach him in any special branch has had to spend many months and many dollars in visiting the different clinics and institutions in various countries, often, too, handicapped with a more or less imperfect knowledge of the language in which the instruction was given. The faculty at Fordham has sought to remove these difficulties of foreign study by bringing the opportunity for such study here. If the student cannot go to the professor, the professor can come to the student, and this is what has happened. The first of these "international extension courses," as they are called, will deal entirely with the nervous system and its diseases. The course will consist of a series of clinical lectures and practical demonstrations conducted daily from September 9 to 28, by various members of the faculty assisted by the following well-known European and American teachers: Nicolas Achucarro, coadjutor of Ramon y Cajal, of Madrid; Carl L. Alsberg, of Washington, biological chemist to the U. S. Government; H. H. Goddard, of the New Jersey State School for Feeble-minded Children; Henry Head, of the London Hospital; Gordon Holmes, lecturer on physiology of the nervous system, London University; C. J. Jung, associate in psychiatry, University of Zürich; Alwyn Knauer, assistant to Professor Emil Kraepelin at the Psychiatrische Klinik, Munich; J. V. May, president of the New York State Commission in Lunacy; Colin K. Russell of McGill University, physician to the Royal Victoria Hospital, Montreal; and William A. White, superintendent of the Government Hospital for the Insane, Washington. The lectures will be in English and will be illustrated by models, photographs, cinematographs, and when possible the patients. There will also be practical courses, for classes of limited size, in special subjects, and on histology, bacteriology, normal and pathological anatomy, surgery, and physicotherapeutics of the nervous system. The fees for the entire course, as announced, will be $40. This unusual experiment in transplanting the European clinic to American soil will be watched with interest, and if it is successful, as it gives every promise of being, it will doubtless mark a new era in medical teaching, as the idea will be adopted and enlarged upon by other colleges throughout the country.

A Specific Toxic Principle in the Blood in Pregnancy.

Those who speculate about autointoxications and hypothetic poisonings in general are always urged to isolate, first the offending substances so that not only may the phenomenon be reproduced at will, but the satisfaction will be afforded of knowing why and how the alleged substances are toxic. No one doubts that sooner or later definite substances will be isolated. It is already clear that these do not differ in any sense from known poisons; and it is significant also that the physiological principles (hormones) which the body produces to regulate its mechanisms are analogous to well-known toxic agencies. In regard to the toxemia of pregnancy we have had until recently not a single clue to a known toxic principle capable of producing the phenomena of that condition. There has been no end of speculation, but not a solitary fact beyond the general knowledge that certain fluids or solids of the gravida could be made to show toxic effects under certain conditions of animal experiment. Last March (*Deutsche medizinische Wochenschrift*, August 8) Grube and Reifferscheid demonstrated before the Niederrheinische Gesellschaft für Natur-und Heilkunde, of Bonn, an ether solution from the blood of a pregnant rabbit. This ether soluble substance was not precipitated by alcohol and was coctostabile. Injected into nonpregnant rabbits in insignificant doses it proved to be a violent poison which usually caused death in convulsions and paralysis. The extract similarly prepared from the blood of the nonpregnant rabbit was nontoxic. The normal pregnant rabbit was nearly immune to the action of this substance. The authors in the presence of the society injected 2 c.c. of the soluttion into the aural vein of a rabbit and caused violent, fatally ending eclamptic convulsions.

Metabolism of Glucose.

While we know that glucose is split up in the body into water and carbon dioxide nothing has been learned as to the intermediate products of this combustion, beyond the fact that lactic acid is somehow concerned therein. It has hitherto been taught that glucose and lactic acid represent the same stage of metabolsm, both having been derived from an unknown substance. Quite recently experiments appear to have shown that the fate of lactic acid is to be transformed to glucose. This transformation is simply an inversion of the one already well known in which glucose is changed to lactic acid. At a meeting last May of the Naturwissenschaftlicher-medizinischer Verein of Strassburg (*Münchener medizinische Wochenschrift*, August 6), Parnas expresses doubt that lactic acid can be changed to glucose, for this result seems to commit the student to the assumption of the possibility of the reversible action of enzymes. That is, if it is meant that the reaction involved is one of chemical equilibrium. On the other hand if a number of intermediate steps could be demonstrated such a transformation could come to pass, as may be shown by studying the opposite changes of glucose to lactic acid which have recently been demonstrated. We may assume that this series of changes is capable of inversion. The reaction would be one of oxidative disintegration, and hence throws considerable light on some obscure points; as, for example, how a muscle can work without oxygen but cannot rest up without it. In phosphorus or arsenic poisoning, again, the toxic substances by interfering with this transformation cause a rapid disintegration of glycogen or glucose, so that lactic acid is excreted.

News of the Week.

Infant Mortality.—There were 358 deaths of infants in New York City reported to the Board of Health last week, as against 361 in the corresponding week of last year. Thus far in 1912 there have been 629 fewer deaths of infants than there were in the corresponding period in 1911.

Poliomyelitis in Buffalo.—During the present epidemic there have been 180 cases of infantile paralysis with 22 deaths in Buffalo. In a recent conference between the local, State and Federal health authorities it was decided to institute a rigid

quarantine of all members of a family in which a case of the disease is discovered.

Hotel Milk.—According to a report made recently by the New York Milk Committee to the Department of Health the milk sold in some of the large hotels and expensive restaurants in this city is unfit to drink. The committee makes a classification of milk on a percentage basis, ranking certified, or grade A, milk as 100; inspected, or grade B, milk as 90; pasteurized, or grade C, milk as 80, and then classing the other grades according to the bacteria they contain. On this basis most of the places visited sold milk that would rank at about 35 per cent., being in the grade established as fit only for cooking and manufacturing purposes. The report has given rise to a lively newspaper war between the committee and the health department, the latter making light of the committee's discoveries, the former accusing the department of laxness and indifference to the health of Mr. Roosevelt and other large consumers of milk in this city.

Reciprocity with New Jersey Reestablished.—At a meeting of the Regents of the University of the State of New York, held last week, it was announced that the medical practice law in New Jersey having been amended so as to meet the standards of the New York medical practice act, the Regents had agreed to the request of the board of medical examiners of New Jersey that reciprocity in medical licenses between the two States be reestablished. The New York requirements were also revised by the addition of the following rule: "After January 1, 1913, an applicant for a medical student certificate qualifying for admission to a medical school shall afford evidence of education including one year in physics, one year in biology, and one year in inorganic chemistry." Drs. F. C. Walker of Brooklyn and A. B. Cooke of Syracuse were reappointed for the term of four years as members of the State Board of Medical Examiners.

The Amendment to the Pure Food and Drug Law, which it was thought would put an end to the unfounded claims of the patent medicine makers', will be ineffective, according to Dr. Wiley. The amendment says that the claims as to curative effects, printed on the labels of the bottles, shall not be false and fraudulent, and this, says Dr. Wiley, will be interpreted as meaning that they may be either false or fraudulent, but must not be both. It is possible to imagine a lawyer contending that the fake statements made by his client were believed by the latter to be true and were therefore not fraudulent. Dr. Wiley says: "The committee had before it a perfectly just amendment drawn in no uncertain terms that not only covered false and fraudulent claims on the labels but also the same claims printed on bill boards or in advertising matter, thus striking a mortal blow at the fakes and frauds which have been a curse to the public. In securing the passage of the Sherley amendment the venders of fraudulent preparations have won a complete victory. It appears that Congress has only given them new life, enabling the roots of fraud and corruption to sink deeper into the soil of legislation, protected of the vested interests but not of the public welfare."

The "Yale Medical Journal" has ceased publication with the issue for August. The reasons given for this are stated by the editors to be "because there is an abundance of available current medical literature for all desiring it, and because of the belief that the value of the *Journal* in the limited field which it has attempted to cultivate is not sufficient to justify the effort necessary for its continued publication." The *Journal* was started in 1894 as an undergraduate magazine with an advisory board of graduate editors. A few years ago, however, the *Journal* began the publication of the proceedings of the Connecticut State Medical Society and at the same time the editorial work was taken up by a board of graduate editors. It may be true, as the editors say, that there is an abundance of available current medical literature for all desiring it, nevertheless there will be a large number of former readers of the *Journal* who will miss greatly the monthly visits of this well edited and readable publication.

The Public Health Service.—The following is the text of the act of Congress affecting the Public Health and Marine-Hospital Service:

"*Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,* That the Public Health and Marine-Hospital Service of the United States shall hereafter be known and designated as the Public Health Service, and all laws pertaining to the Public Health and Marine-Hospital Service of the United States shall hereafter apply to the Public Health Service, and all regulations now in force, made in accordance with law for the Public Health and Marine-Hospital Service of the United States shall apply to and remain in force as regulations of and for the Public Health Service until changed or rescinded. The Public Health Service may study and investigate the diseases of men and conditions influencing the propagation and spread thereof, including sanitation and sewage and the pollution either directly or indirectly of the navigable streams and lakes of the United States, and it may from time to time issue information in the form of publications for the use of the public.

"Sec. 2. That beginning with the first day of October next after the passage of this act the salaries of the commissioned medical officers of the Public Health Service shall be at the following rates per annum: Surgeon General, six thousand dollars; Assistant Surgeon General, four thousand dollars; senior surgeon, of which there shall be ten in number, on active duty, three thousand five hundred dollars; surgeon, three thousand dollars; passed assistant surgeon, two thousand four hundred dollars; assistant surgeon, two thousand dollars; and the said officers, excepting the Surgeon General, shall receive an additional compensation of ten per centum of the annual salary as above set forth for each five years' service, but not to exceed in all forty per centum: *Provided,* That the total salary, including the longevity increase, shall not exceed the following rates: Assistant Surgeon General, five thousand dollars; senior surgeon, four thousand five hundred dollars; surgeon, four thousand dollars: *Provided further,* That there may be employed in the Public Health Service such help as may be provided for from time to time by Congress."

Dr. Georges Rambaud of the Pasteur Institute in this city has been awarded by the French Government the title of Chevalier of the Legion of Honor.

Dr. S. R. Klein, formerly professor of histology and embryology at the Fordham University School of Medicine, New York, has been placed in charge of the new research laboratories of the Hahnemann Medical College, Chicago.

The Plague in Cuba and Porto Rico.—Cuba has been declared by the Public Health Service to

be free from the bubonic plague, and all restrictions on passenger traffic between the island and the United States have now been removed. The last case in Cuba was discovered on July 22, the man dying on July 27. Porto Rico also has reported no cases for some time, but the quarantine restrictions have not yet been raised. The killing of rats and the rat-proofing of buildings in San Juan are still going on.

Dr. Edgar Jones, the oldest physician in England, died on August 26, in London, at the age of 102 years.

Alcohol in Patent Medicines.—Over three hundred patent medicines in the shape of tonics, stomach bitters, nervines, etc., are now classed by the Internal Revenue Department as alcoholic beverages and taxed accordingly. The commissioner has recently added sixty to the list of so-called remedies which are insufficiently medicated to render them unfit for use as beverages, and are accordingly classed as the latter. The list previously contained upward of 250 preparations of the kind.

Obituary Notes.—Dr. William J. Parker of Jersey City died of typhoid fever on August 28 at the age of 54 years. He was born in Jersey City and was graduated from the Bellevue Hospital Medical College in 1879. He had always been prominent as a military surgeon in the National Guard. He was appointed First Lieutenant and assistant battalion surgeon, Fourth Regiment, N. G. N. J., in 1893. He was promoted to major and regimental surgeon in 1895 and in 1904 he became Lieutenant Colonel and staff surgeon of the First Brigade of New Jersey. In 1910 Dr. Parker was appointed surgeon on the staff of Gen. P. Farmer Wanser, commander of the National Guard of New Jersey.

Dr. George H. Rue, a homeopathic physician of Lexington, Ill., died at his home on August 5 as the result of an acident.

Dr. J. Howard Beck died at Philadelphia on August 15 at the age of fifty-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1882. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania and of the American Medical Association.

Dr. Richard M. Fulkerson of Mounds, Ill., a graduate of the Eclectic Medical College of Cincinnati, Ohio, in 1870, died at his home suddenly on August 11, aged 73 years.

Dr. George S. Morris of Arkansas City, Kan., a graduate of the Medical College of Ohio, Cincinnati, in 1871, died suddenly in his office on August 12.

Dr. George Washington Simpson, physician and clergyman, of Baltimore, Md., a graduate of the College of Physicians and Surgeons, Baltimore, in 1873, a member of the American Medical Association and the Maryland State and Baltimore City Medical Societies, and for many years a chaplain in the United States Army, died at his home on August 18, aged 71 years.

Dr. Henry Stuart Nolan of West Somerville, Mass., a graduate of the Tufts College Medical School, Boston, in 1906, died at the Deaconess Hospital, Boston, after a long illness on August 18.

Dr. Andrew J. Brockett of Cleveland, Ohio, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1862, a surgeon in the United States Army during the Civil War, and a member of the American Medical Association and of the Ohio State and Cuyahoga County Medical Societies, died at his home on August 11, aged 76 years.

Dr. Franklin R. Garlock of Racine, Wis., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1870, a veteran of the Civil War, and a member of the Wisconsin State and Racine County Medical Societies, died at his home on August 15, aged 72 years.

Dr. Charles Thorndike Parker of this city died of pneumonia at his summer home, South Hamilton, Mass., on August 31, aged 54 years. He was born in Boston and was graduated from the College of Physicians and Surgeons in this city. He retired from practice a number of years ago.

Dr. Frederick F. Hoyer of Tonawanda, N. Y., died August 23 at the age of 90 years. He was a graduate of the Medical Department of the University of Buffalo in 1849. He was an ex-president of the Erie County Medical Society and was for a number of years health officer of Erie County.

Dr. Charles G. Criser of Warm Springs, Va., a graduate of the University College of Medicine, Richmond, Va., in the class of 1899, died at his home of apoplexy August 18, aged 41 years.

Dr. B. M. Alford of Alameda, Cal., a graduate of the Tennessee Medical College in 1856, a Confederate surgeon during the Civil War, and for twenty years a surgeon of the Southern Pacific and Santa Fe railroads, died at his home on August 14, aged 79 years.

Dr. R. E. Martin of Milwaukee, Wis., a graduate of the Chicago Homeopathic Medical College in 1886, and a former health commissioner of Milwaukee, died on August 21, aged 47 years.

Dr. Paul Emile Archinard of New Orleans died at his home on August 23 after a long illness, aged 53 years. He was a graduate of the Medical Department of Tulane University in the class of 1882, and was professor of diseases of the nervous system in the same university at the time of his death.

Dr. Lawson Harrill of Statesville, N. C., a graduate of the Jefferson Medical College in 1861, a veteran of the Civil War, and for many years State smallpox inspector, died at his home on August 26, aged 75 years.

Dr. C. Annette Buckel of Piedmont, Cal., a graduate of the Woman's Medical College of Pennsylvania, a superintendent of nurses in the Union Army during the Civil War, died at her home on August 17, after a long illness, aged 79 years.

Dr. August Rauscher of Murray, Utah, a graduate of the University of Vienna in 1855, died at his home on August 15, aged 79 years.

Correspondence.

A NEW PHASE OF FAULTY MEDICAL TRAINING.

To the Editor of the Medical Record:

Sir:—The Carnegie College Investigation pointed out the defects of colleges in buildings, appliances, and hospital connections, and stopped there. Mr. Flexner apparently thinking that these were all the great obstacles to the progress of medical training. Now, another inquiry has started which promises a better understanding of the subject, and is certainly more scientific and along the lines of exact facts.

Several different State boards have begun to collect figures concerning the attainments of students of various colleges, in particular branches of medicine. It has been noted that graduates of certain colleges rank very low in chemistry, practice of medicine, or some other branches. In other departments they stand very high, and an average brings them up to a passable standard. Other colleges show the same peculiarities. Some stand very low in practice and high in surgery. Some excel in anatomy and fail in pathology, and so on through the list. In one college where anatomy was taught by a very distinguished man the graduates were invariably low in their standing. In another college where pathology and bacteriology were taught by distinguished men, who had done original work, the graduates were below the average. In another college where other branches were taught by really strong men the students failed in these departments, but in others excelled. Some of the colleges with extraordinary facilities and appliances for teaching certain subjects turned out students with a very low comprehension of these branches.

These facts indicated other causes than trained professors with remarkable building and appliances. The trouble centered back on the teachers, who lacked enthusiasm, lacked pedagogic instincts, and taught these subjects in a perfunctory way. Many of them were exceedingly strong men, but they failed to arouse the instinct of learning in the student. They were negative men who could not impart the art or science of their topics so that the student could retain them. One of these inquiries covering the graduates of two years in several Eastern colleges showed that certain colleges graduated very inferior students in certain branches, and that in certain other branches the students ranked very high, irrespective of hospital connections, eminent teachers, and unusual facilities for teaching. There is a new field open in this direction, which will attract attention in the near future.

In every college there are certain men who fail to make their subjects attractive to the students, not because they are incompetent or do not know the subject, but because they have not the faculty of clearly impressing the facts. Men who are salaried to teach and do nothing else are often very learned, vague, and impractical, and while able to teach their separate branches in a highly scientific way are little better than text-books or compends. They present the truths in exact logical manner, but the setting is bad and no impression comes from it.

Thoughtful men assert that medical college reforms must begin with the teachers, and that something more is needed than elaborate apparatus, hospital connections, and bacteriological appliances. The value of college education depends more on the teachers than these. A small Western school where all the professors are practical men became noted for the high standing of the students that it graduated. The Carnegie research turned the school down as inferior and lacking, because it had no showy externals, and yet literally the graduate students ranked higher before the State boards as a class than others who had been graduated from the best colleges. It was the teachers and professors who made it what it was.

The State boards can do a great service if they will tabulate their experience and ratings of graduates on individual branches, and this will be a new movement towards a higher grade of training.

T. D. Crothers, M.D.

Hartford, Conn.

UNTO THE SECOND AND THIRD GENERATION.

To the Editor of the Medical Record:

Sir:—Thinking the following may be of interest enough to record in your columns I am writing you a short history of a case of mine. Mr. B. some thirty-six years ago contracted syphilis and was, as he thought, successfully treated for it, though now at sixty-eight years of age he has had one or two strokes of paralysis, and one—the oldest—child has had recurrent attacks of interstitial keratitis. Eight other children are above the usual run in development and have always enjoyed more than average good health, while the object of my story is a perfect picture of health in every way and a most painstaking search of her life shows absolutely nothing that can be attributed to specific infection.

The sixth daughter (about twenty-four years old), Mrs. F., some three years since married a perfectly healthy man who again gives a specific free history. Last November I delivered Mrs. F. of a seven and a half pound baby who seemed fat and healthy but whose liver was very prominent. Knowing her father's history, I was not at all surprised when its grandmother some four weeks later called my attention to a pemphigus of the palms and soles and also to a severe rhinitis that gave the baby a great deal of trouble. To make sure of my diagnosis I refrained from any specific treatment and ten days later the baby effloresced like a severe case of measles and the family were very much alarmed at its condition. Under the iodides of mercury, potassium, and iron both to the baby and its mother, the case rapidly improved, and after four weeks I could no longer prevail on the parents to continue its use, as the baby seemed entirely normal and has continued so ever since.

OUR LONDON LETTER.

(From Our Regular Correspondent)

INCLEMENT SUMMER—INSURANCE CAMPAIGN, RESIGNATIONS FROM ADVISORY COMMITTEE—ASYLUMS BOARD—HOSPITAL ABUSE—ARTHRITIS IN THE STONE AGE—EXHIBITION RELATING TO CONSUMPTIVE INSTITUTIONS—ROYAL MEDICAL BENEVOLENT FUND—NEW SECTIONS AT ROYAL SOCIETY OF MEDICINE—OBITUARY.

London, August 16, 1912.

The weather—always a prominent subject with us—is this year more than for a long period the topic which almost monopolizes conversation. The wettest July since the late eighties is followed so far by the coldest August for fifty years and this accompanied by severe storms of wind, rain, thunder, in fact all varieties of atmospheric disturbance. It is a trying time for many patients, who talk about autumnal and wintry weather. Temperatures from 12° to 22° below the average have been registered day after day. Intervals of sunshine have again and again raised our hopes of a permanent change to something like summer, but have soon ended in disappointment. This week has been one of the worst. Two days ago the thermometer crept up to 63° Fahr. in the morning but fell to 52° in the afternoon when it ought to have been 70°. The provinces report similar conditions, and the worst of it is that the experts assure us there are no signs of improvement. People tell me it is as bad and worse in many parts of Europe and quote the me-

teorological statistics, but the figures do not make me any warmer.

The insurance campaign proceeds steadily. The British Medical Association, as you know, called upon the members it had nominated to the Advisory Committee to withdraw. These gentlemen, thirteen in number, have done so. At the same time non-members were asked to support the movement and fourteen nominated by the Government have also withdrawn. On the other hand, Dr. Addison, M.P., who is commonly credited with having given some advice as to terms to Mr. Lloyd George, with thirteen other gentlemen have declined to resign, stating that having considered their position fully they are of opinion that for the present it is their duty to remain.

The report for 1911 of the Metropolitan Asylums Board was issued last week and contains important statistics of which some may be mentioned. The patients admitted to imbecile asylums numbered 1,038, being an increase of 125 over 1910. The total number of inmates remaining on December 31 was 7,270, an increase of 228. This was the first year since 1903 that the admissions exceeded 1,000, the average number for 7 years having been 871. The number this year under 16 years old was 200, under 5 years 40; of adults 249 were over 70, between 70 and 80 there were 178, between 80 and 90 were 66, and 5 were over 90. The admissions to infectious hospitals numbered 21,138, an increase of 5,900, the discharges 18,778, an increase of 3,550 over 1910.

Two events in the board's history for the year claim notice, one being the transfer of the casual poor of the metropolis to the care of the board, the other the adoption of a new scheme for the accommodation and classification of the feeble minded. In regard to the latter it is stated that the reports of the children's committee have prepared the way for the recognition of the facts that the feeble minded in their care can never be sufficiently improved to take a place in the outside world so that the community must undertake the burden of their permanent support. Further, there has been much overlapping of cases claimed as imbeciles and feeble minded. It is proposed to bring all grades of infections under the jurisdiction of a single committee and to reserve the Darenth Industrial Colony entirely for improvable imbeciles. The result attained at Darenth in the past, in spite of the retention there of hopeless imbeciles who are now to be removed, the board considers affords the best augury for the future of the colony.

Hospital abuse, a long-standing and never absent subject of complaint on the part of working practitioners, has lately been more insistent. A report of a committee to inquire into the out-patient system of the London hospitals has been published on behalf of King Edward's Fund. It is signed by Lord Mersey and the Bishop of Stepney, and deals with hospitals within a radius of nine miles from Charing Cross. There are 12 hospitals with schools which treated 884,634 out-patients; 16 without schools and 355,589 out-patients; 7 children's hospitals treated 156,352; 30 special hospitals, 276,916; about 28 other smaller hospitals about 102,000. Here there is a total of 1,775,491 sick persons receiving gratuitous aid, but this is supplemented by about 52 provident and 54 nonprovident dispensaries, besides 43 under the Poor Law service.

The committee do not think the system is abused by "really well-to-do people." One may hope not, indeed. But they admit that practitioners probably have good grounds for thinking many could, without hardship, afford to pay moderate charges. There is stronger evidence that large numbers could provide for themselves by provident dispensaries and clubs. They admit, too, that with the lowest payment of which evidence was given them, the necessary attention could not be given and the medical status and efficiency must degenerate to the great disadvantage of the poor. The committee submit that any scheme of reform should include reduction of numbers, partly by excluding those who can pay and trivial cases; cooperation with general charitable work and Poor Law assistance; safeguard for medical education and science. Co-ordination need not be mere refusal of help with perhaps adding danger of delay, but might take the form of reference to a more appropriate agency and so secure that all classes of cases were provided for. Moreover, cooperation should supplement the medical treatment when illness is due to other forms of distress, and to ensure that the Poor Law is only resorted to in cases beyond the reach of voluntary assistance.

A somewhat different tone prevailed at the Liverpool meeting where the subject was discussed by those well qualified to speak of it. The statistics of the local institutions indicated that people of small means were not the only applicants for hospital and dispensary treatment. It was said that these institutions gave gratuitous advice in the year 1910 to nearly 30 per cent. of the population. This would not include those treated under the Poor Law, said to be about 10 per cent. Inquiries made by the Voluntary Aid Council showed that 25 per cent. of the out-patients at the large general hospitals admitted they were earning over 30 shillings per week.

Dr. M. Dewar of Edinburgh contributed a paper on the subject, in which he urged that there were poor people enough who were compelled to take the out-patients' place and gave considerable work to the medical officers, without counting those who could pay general practitioners, and even specialists. Unfair competition between charitable institutions and private doctors was sapping the independence of whole classes. Apparently well-to-do people could generally be seen in the out-patients' waiting rooms. He mentioned a case, which must surely be exceptional, in which the medical officer of a district had introduced a gentleman who had an income of £800 a year to a hospital for treatment. I hope that medical officer was present at the meeting and has profited by the lesson.

Dr. Parkinson said much of the trouble arose because each hospital was an isolated unit and they ought to cooperate with each other and with other agencies for assisting the sick poor. The only people who did not see abuse were the lay members of committees. Many patients questioned about their income told flagrant lies. One of the first duties of hospitals was to see that funds entrusted to them for charitable purposes were expended for that purpose.

Dr. Rentoul blamed the doctors for bringing these conditions on themselves by contracting with clubs at ridiculous prices—5/, 4/, and even 1/6 a year had been accepted, and actually a Liverpool tea dealer had made the experiment of offering free medical attendance to anyone who bought 1/6 worth of tea. He declared doctors in Liverpool got

the Watch Committee to order that in accidental cases the ambulance should not take the injured home but to the pay wards of the hospital. Some people said that was not true, but he repeated "it was true." In some Lancashire towns arrangements were made that patients taken into the hospitals could have their family doctors attend them. Why should not that system be generally adopted?

Dr. Kingsford suggested that the high fees for operations and the excessive charges in nursing homes drove into hospitals many who would be willing to pay moderate prices.

It is reported that among the neolithic skeletons found near Vendrest (Seine-et-Oise) are some which show distinct traces of arthritis deformans. Some of the fragments may very likely have belonged to a single individual, as the number is not great. There are enlargements, however, on a patella, a wrist, several fingers and toes, and two ribs. It is interesting to notice that the disease prevailed in the stone age, though it has long been conjectured that it was ancient. Traces of it have been recorded as seen among the remains of the cave bear. Very rarely has it been mentioned among prehistoric remains of Egypt. Perhaps the climate may have been more propitious.

An exhibition of materials relating to sanatoria, tuberculin dispensaries, and other articles employed in furnishing such institutions is to be opened on the 26th inst. at the offices of the Society of Medical Officers of Health.

The Royal Medical Benevolent Fund is henceforth to be the name of that heretofore called British, the King having been pleased to approve of the change.

The Royal Society of Medicine is arranging for two new sections, ophthalmology and tropical medicine, to be opened early in the winter session.

Mr. Stanmore Bishop, F.R.C.S., of Manchester, died on the 25th ult., aged 64. He was surgeon to the Ancoats Hospital and president of the Manchester Clinical Society, and held a high position in abdominal surgery and gynecology. He contributed many papers to the societies and journals, chiefly on these departments of surgery.

Professor J. J. Charles has died at the age of 67. He was professor of anatomy and physiology at Queen's College, Cork, from 1875 to 1907. He was also examiner in the Royal University of Ireland.

Dr. J. E. Meredith, consulting physician to the West Kent General Hospital and who held other offices in Maidstone, died at St. Leonards. He was a graduate of Dublin, in arts and medicine.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent)

CHOLERA CARRIERS—BACILLARY DYSENTERY—RINDERPEST—BERIBERI—PERSONAL.

MANILA, P. I., July 19, 1912.

It has long been questioned whether the frequent outbreaks of cholera which have occurred in the Philippine Islands in the past have always been due to infections which originated in the country. Since 1908, when the first cholera carriers in Manila were found, it has been suspected that possibly some cholera carriers were introduced from nearby foreign countries. On account of the seven-day plague quarantine which is imposed against all steerage passengers arriving from Amoy and Hongkong, an excellent opportunity was afforded, while this detention was going on, at the Mariveles Quarantine Station, to have the stools of such passengers examined. On account of the infrequency with which cholera is found among Chinamen, it was not thought likely that any person of this nationality would be found to be a cholera carrier. It is, therefore, of considerable interest to report that the 557th case examined was found to harbor virulent cholera organisms. The Chinaman had left Canton, China, seven days previously, and, so far as could be ascertained, he was in good health. He was kept under observation for a period of ten days, at the end of which time his stools were found to be negative. It has frequently been held that in former outbreaks of cholera in the Philippines the disease often began among Japanese, but no satisfactory explanation could be made. In view of the experience had with the Chinaman, it seems probable that cholera carriers may have been present among incoming Japanese passengers. Since this first cholera carrier was reported the stool examinations of four others showed vibrios, but upon careful laboratory examination made at the Bureau of Science they were shown not to be the vibrios of Koch.

Acute outbreaks of bacillary dysentery are reported from many sections of the Philippines. The disease is, evidently, spreading in all directions, and on account of its mortality not being as high as that for cholera, it does not cause the same amount of alarm and outbreaks are frequently well under way before they come to the notice of the health officials. Laboratory examinations show that the organisms are usually either of the Shiga or Flexner type.

Manila has again been invaded with rinderpest, outbreaks of the disease having occurred in several local dairies and caused great loss. This is of interest to medical men because it was, at first, alleged that the children who drank milk from rinderpest animals developed severe diarrheas and in some instances died. Investigation of this matter has shown, however, that the children in question died of bacillary dysentery, which their history showed was contracted from sources not connected with the milk supplied by the dairies in which the rinderpest occurred. The veterinarians state also that as soon as an animal becomes sick with rinderpest the secretion of milk stops. The matter is still under investigation by the Bureau of Health.

Referring further to the question of beriberi, the recent experience which has been had at the Culion Leper Colony adds considerable additional confirmation to the now generally accepted theory that this disease is caused by the continuous use of rice as a staple article of diet, from which a certain portion of the cortex, or pericarp, has been removed. During the autumn of 1911 the Philippine Government found it necessary to purchase large quantities of rice in order to prevent unduly high prices being charged by dealers, owing to the shortage which prevailed. This rice was of the polished variety and was afterward used in Government institutions, among which was the Culion Leper Colony. Prior to the use of this rice the average death rate among approximately 2,500 inmates of the colony for the preceding four months was 28 per month. The use of the rice was begun during the latter part of November and continued until early in February. During January the death rate commenced to increase and by March it had reached 92 deaths per month, or an increase of over 200 per cent. During the latter part of February large quantities of mongoes (a local legume that resembles a lentil and is rich in nitrogen) and other foods which are believed to

contain the beriberi preventing principle, were used with the white rice and about the middle of March the use of partially polished rice, which contained at least 4 per cent. of phosphorus pentoxide was begun and has been continued to date. During the latter part of March a decrease in the number of beriberi deaths began to take place and during April the total deaths at the Colony had again fallen to 25 per month. During May the population was increased by new arrivals to 2,600 and the total number of deaths was 29.

Dr. Richard P. Strong, who is just recovering from his recent illness, will leave the Philippine Islands for a vacation in Europe and America on July 29.

Dr. W. E. Musgrave, the chief medical officer of the Philippine General Hospital and dean of the College of Medicine and Surgery of the University of the Philippines, has been confined to the hospital by sickness. He leaves Manila on July 20 for a month's vacation in Japan.

OUR BERLIN LETTER.

(From Our Regular Correspondent)

SCHOOL AND TUBERCULOSIS—CAMPAIGN AGAINST LATENT TUBERCULOSIS—SPECIAL CLASSES AND OPEN-AIR SCHOOLS—SCHOOL DENTAL CLINICS.

BERLIN, August 1, 1912.

SCHOOL and tuberculosis was the subject of an instructive address delivered before the fourth meeting of the Society of School Hygiene by Professor Kirchner. As an introduction he presented figures to show that the general reduction in mortality has gone hand in hand with the progress in hygiene. From 1886 to 1910 the mortality fell from 29 to 16 per thousand. The cause of this diminution has been the reduction in the prevalence of infectious disease. The death rate from tuberculosis has fallen markedly; whereas in 1875 there died from this disease 32 out of 10,000 individuals, in 1911 only 15 succumbed to it. At the present time there are 60,000 deaths annually from tuberculosis in Prussia. In 1905 the speaker had pointed out that the reduced death rate from tuberculosis occurred only in males at certain age periods for whom the great social hygienic measures are operative. On the other hand tuberculosis mortality has not decreased so far as women and children are concerned; in fact, up to 1902 it had increased. From this observation it would be erroneous to conclude that tuberculosis is a school disease. Open tuberculosis is very seldom found in the schools. But latent tuberculosis is very common among school children and must be combated by means of every known resource. The first requisite is that children with open tuberculosis must be excluded from the schools. This can be accomplished only when the general notification of tuberculosis is carried out. Since there is no notification law in Germany, the duty develops upon the school medical authorities to exercise a strict surveillance lest cases of open tuberculosis be permitted to attend school. The campaign against latent tuberculosis lies in the hands of the school physicians, who examine every pupil on entering school and who follow the suspicious cases through the entire school period. There is a need for special classes for these suspicious cases. A few cities have set a good example by the establishment of open air schools, as in the case of Charlottenburg with its "Waldschule." The good results obtained in the latter should lead to a general establishment of these schools. Moreover, all classrooms should be kept scrupulously clean. No one, not even the janitor, should be permitted to live in the school. There should be a general establishment of school lunches and school baths. School dental clinics have a special significance with reference to the prevention of tuberculosis, for good teeth ensure better resistance against disease and the better utilization of nutriment. Not to be overlooked is a thorough grounding of the pupils in the principles of hygiene, not only for their own sake but as a means of disseminating this information in the household.

Progress of Medical Science.

Boston Medical and Surgical Journal.

1. Blood Transfusion: Indications, Methods and Results. B. Vincent.
2. Intrarectal Rupture of Suppurating Sinus from Hip Joint Disease. R. W. Jackson.
3. The Doctor Who Volunteers For Military Service in Time of War. C. C. Foster.
4. A Study of Thirty-Nine Cases as Regards the Intestinal Length and Nutrition. L. T. Swaim.
5. A Private Obstetrical Record. J. R. Torbert.

1. **Blood Transfusion.**—B. Vincent discusses a few practical points in regard to the use of transfusion and the best methods of operation. The indications are acute hemorrhage after injury or operation and in ectopic gestation; the uterine hemorrhages of childbirth, miscarriages, or fibroids; the severe bleedings from ulcers in the stomach, duodenum, or intestines; shock; gas poisoning; the bleeding occurring in deeply jaundiced individuals, in hemophilia, and in hemorrhagic disease of the newborn. Transfusion is less clearly indicated in the secondary anemias which are not due to the loss of red corpuscles to the body. The cause of the anemia is too often a pathological condition which is incurable or not altered by the transfusion of blood. Illustrations of the stimulating effect of transfused blood are found in its use as a preparatory measure before operations on weak patients, in pellagra and in certain cases of prolonged suppuration with profound anemia. In such instances the beneficial effect of the transfusion is obtained by increasing the patient's resistance and augmenting the natural forces which combat the progress of the disease. In purpuric conditions of obscure etiology transfusion is not indicated by the results which have been secured up to the present time. It may prove to have a place in the treatment of the purpura when one has a better understanding of the diseases in which purpuric hemorrhages occur. In pernicious anemia, leucemia, certain toxemias, acute infections, and malignant disease the negative results are sufficiently definite to contraindicate transfusion in these cases. In spite of its comparative safety, transfusion should be considered a measure of last resort to be applied when simpler means have failed and only in those cases in which there is a rational basis for its use. Success in the performance of transfusion is more dependent upon adequate experience than any special method. In adults the Elsberg canula is evidently the best for the average surgeon. In infants the operation is done with the least difficulty by means of glass tubes of proper length and size.

2. **Intrarectal Rupture of Suppurating Sinus.**—R. W. Jackson concludes that intraanal or intrarectal rupture of a coxitic sinus occurs rarely but not with extreme infrequency. Such opening involves probably a considerable degree of mixed infection of the joint beyond what would occur if the opening were external. Likewise tuberculous infection of the rectum might arise. The intraanal opening is quite easily treated and much of the mutual risk of infection may be removed. The intrarectal opening is in

most cases (unless the sinus approaches from low down) too high to turn aside in any way and give an external discharge and consequently the risk must continue. If an operation is performed in this instance it is likely to create at once a complete rectal fistula where none existed before, because of the surgical difficulties in the way of securing permanent closure of the internal opening. It is a very rare and most unfortunate occurrence for such an abscess to point both externally and internally; and an external incision should be made if one is sure that internal rupture has not occurred, but this external incision should be avoided, if possible, if internal rupture has occurred, because of the fistula thereby created. However caused, such a fistula is a particularly troublesome one, and the wisdom of trying to better it surgically is fairly debatable ground.

4. Intestinal Length and Nutrition.—L. T. Swaim studied thirty-nine subjects at autopsy to find out whether or not the length of the small intestines had any relation or bearing on general nutrition, and also to find out what the variations in length actually were. As the result of his observations the author concludes that ptosis is present probably in many more cases than is realized, in 9 out of 29 cases. The size of the stomach varies enormously; the tubular stretched stomach is present in most of the cases of ptosis (6 out of 9), and the lesser curvature can be greatly stretched downwards. The small intestines vary greatly in length, from 10 feet 6 inches to 25 feet 10 inches, averaging 19 feet 3 inches. The length has only a slight effect on the nutrition. There is a tendency to a greater accumulation of fat the longer the intestine is and vice versa. The large intestines vary also, averaging 5 feet 3 inches, with extremes of 3 feet 8 inches to 8 feet 5 inches. When the stomach is low the large intestine is apt to be longer and the cecum large and pendulous, the greatest length being in the transverse colon and sigmoid. The total average length of the entire intestines is 24 feet 6 inches. A rather significant fact is that not only were the hollow viscera displaced, but even more often the solid viscera, such as the liver, which was below the costal border in 20 cases.

1. The Inheritance of Acquired Characters. J. Wright.
2. Health Conditions in the Canal Zone. S. H. Brown.
3. The Fee Book of an Irish Physician of the Seventeenth Century. J. J. Walsh.
4. A History of Surgical Hemostasis. W. C. Borden.
5. Some Experiences with the Lessilur-Prirey Test. B. G. R. Williams.
6. A Poisoned Blood Stream. L. A. Merriam.
7. Ten Sex Talks to Girls. I. D. Steinhardt.
8. The Technique of Radiography. J. Friedmann.

2. Health Conditions in the Canal Zone.—S. H. Brown presents statistics which indicate that the health conditions of the isthmus compare favorably with those of almost any other industrial section of a like population; indeed, they are vastly superior to many of the latter conditions. When it is considered that the sanitary department covers so many fields the expense is trivial. No other health department exercises such rigid or conscientious surveillance over the people in its charge. It is suggested by the author that when the canal is completed and the sanitary department has assumed an automatic character, its several heads could be placed in charge of the larger American cities with the same authority vested in them as at present in the Canal Zone. Perhaps one might then persuade our own people that flies and mosquitos are not necessities and that their removal is not an interference with any one's constitutional prerogatives.

5. The Albumin Reaction of Sputum.—B. G. R. Williams states that: 1. The positive albumin reaction in a sputum in which the disease is not acute, points very strongly to the presence of pulmonary tuberculosis. 2. The test is of little or no value when one is attempting to differentiate acute bronchitis or pneumonia from galloping consumption. 3. The sputum from a case of pulmonary edema secondary to renal or cardiac difficulties may show albumin, but the differentiation from phthisis should have preceded the positive test by many months. 4. Even though albumin be found in gangrene and bronchiectasis, these conditions are not usually mistaken for early tuberculosis. 5. A positive reaction invariably enables one to rule out chronic bronchitis, and as this condition is likely to be mistaken for tuberculosis, the test should prove valuable. 6. The reaction, though not an extremely early one, seems to be present as early as tubercle bacilli are set free in the sputum and in some cases precedes the latter. The author believes that sulphosalicylic acid is a more delicate reagent and promises to be of more service than heat and nitric acid. 8. The test, though a chemical one, should be performed with bacteriological precautions. 9. This test will doubtless find future favor with the general practitioner.

6. A Poisoned Blood Stream.—L. A. Merriam believes that chief among all the known causes of disease is a chemical or electrical change in the constituents of the blood stream, as the result either of influences of the environment, or of poisons from foods and waste matters, causing further changes in the cellular structure of the body. Overfeeding, faulty methods of eating, and improper combinations of foods, with imperfect elimination of waste substances, are the essential factors in a poisoned blood stream. Overfeeding, even if there are perfect insalivation and perfect digestion of starch foods and proteids, with perfect assimilation, may cause constipation, overburdening of the liver, and the overloading of the blood stream with nutriment which undergoes chemical changes in the intestines or blood, and with the waste products of repair is changed into purin bases and other chemical substances. These, not being changed into the usually harmless end products for elimination, render the blood stream impure, alter the internal secretions, and make the blood a suitable culture medium for bacteria.

4. Experimental Devascularization of Intestines.—J. S. Horsley and C. C. Coleman report their experiments on devascularization of segments of intestines with and without mechanical obstruction, and conclude as follows: The view usually held that bowel with impaired nutrition can be easily permeated by bacteria has not been borne out in the experiments. In no instance did the dog die under three days except when perforation had occurred and the bacteria and other intestinal contents had been thrown in an overwhelming amount into the abdominal cavity. In such cases death took place in a few hours. A short segment of intestine in a dog when deprived of its nutrition

if thoroughly protected by omentum, may be nourished through the omentum and maintain its integrity. It has been taught that if even a small portion of intestine becomes detached from its mesentery, gangrene and a fatal result necessarily follow. In a dog this does not appear to be true. The occurrence of mechanical obstruction along with gangrene, as would occur in many clinical cases such as strangulated hernia, intussusception, and volvulus, adds a great deal to the gravity of the situation. Devascularization of a segment of bowel without obstruction, as when the intestine is severed from its mesentery by a wound, seems to be much less serious than when there is obstruction. If such a segment is short and is protected by omentum, the condition appears to be compatible with recovery.

5. Injurious Effects of X-Rays.—A. Ravogli describes the lesions that may be produced by the *x*-rays, and presents illustrative cases. In one, epithelioma followed the use of the *x*-ray in the treatment of lupus erythematosus, and a carcinoma was produced by its use in a case of lupus vulgaris. The author discusses similar reports from the literature and concludes that Röntgen therapy is accompanied with more or less danger. This statement is not made for the purpose of discouraging anybody from the use of so powerful a physical remedy, which can be of benefit in a great many diseases, but only to call attention to the great care which has to be used with the *x*-rays. In some cases the patients have been trusted to inexperienced office attendants, and the physician has noticed the danger only when dermatitis had already set in. When, with the *x*-rays, no improvement or no progress is obtained in the treatment of the disease, it is better to stop and change to some other method of treatment; otherwise danger is lurking and will soon be looming up. When a radiodermatitis has begun, if it is of first degree, bathing the parts with a 2 per cent. solution of aluminum subacetate or of sodium bicarbonate will diminish the itching and the burning sensation, and the skin in a short time will return to the normal condition. If the burn is of second degree with the formation of blisters the continuous bathing with soothing solutions, the opening of the blisters and the other treatment as for any burn will be sufficient. When ulceration sets in recovery is difficult. The best way for a speedy recovery is the excision of the whole ulcerated surface.

8. Appendicitis Complicating Pregnancy.—P. Findley reports fifteen cases in which this complication was present. In all but one of these there had been previous attacks. Six of the cases were mild attacks in which the patients recovered without interruption of pregnancy. Of the others, six recovered and three died. Five cases occurring in the puerperium were unusually severe. Two of the fatalities were from septic peritonitis and one was from bronchopneumonia. One of these cases was not operated on. In the majority the attacks recurred in the early months of pregnancy. In no case was pregnancy interrupted after the removal of the appendix. Pregnancy has probably no influence in inducing a primary attack of appendicitis, but favors renewed attacks. Women who have had appendicitis prior to pregnancy will in 50 or 60 per cent. of cases have more or less trouble with the appendix in future pregnancies. As the condition tends to be specially destructive and dangerous in pregnant women, the earlier the operation is performed the better. According to Wagner, the mortality of non-operated severe cases is 77 per cent. as against a mortality of 6.7 per cent. in all cases, severe or otherwise, in which operation is done within the first forty-eight hours, a record not exceeded in operating for appendicitis uncomplicated by pregnancy. Doubtless this percentage of maternal mortality would be still further reduced were the patients operated on within the first twenty-four hours.

10. Nephritis in Pregnancy.—J. B. DeLee discusses the inflammations of the kidneys complicating pregnancy. In addition to the ordinary forms there are the so-called pregnancy nephritis and the kidney changes occurring in eclampsia. Primary acute nephritis may develop during gestation from the same causes ordinarily producing it, and chronic nephritis may have preexisted, hardly recognized by the patient until the added strain thrown on the kidneys brings it to light. Chronic parenchymatous nephritis is always unfavorably affected by gestation, and is almost always observed in acute exacerbation. It begins in the early months, unlike the nephritis occurring with eclampsia, convulsions occur in one-third of the cases, and labor has a bad effect on the disease and, if prolonged and exhausting, serious damage to the kidneys may result, especially if an anesthetic is used. The puerperal condition does not improve it, and repeated pregnancies hasten death. Chronic interstitial nephritis is more frequent than the other form and convulsions are less often seen. Albuminuria, as shown by the coarser test, is of considerable diagnostic significance. Low urea output is relatively less important, but if the excretion is less than 6 grams careful search should be made for renal disease. Mother and child are both seriously endangered by chronic nephritis and the prognosis should be guarded. A combination with heart disease is fatal. Women with chronic nephritis should not marry, and if married should not have children. If pregnancy occurs in them they should be carefully watched. If the kidney disease is discovered late in pregnancy, the consensus of opinion favors tiding the patient along until threatening symptoms occur and then inducing premature labor. If discovered before the child is viable the pregnancy should be discontinued, though if it occurs nearly at the time when a living child can be born, pregnancy should be carried along for a few weeks to save a living child if possible. During labor nephritics require special care, and the heart's condition should be closely watched. Pulmonary edema or symptoms like cerebral embolism may call for a rapid delivery.

11. Intrapelvic Reconstructive Work.—W. F. B. Wakefield pleads for the use of a more careful technique in reconstructive intrapelvic work. Experience has taught that extensive adhesions may be formed from simple mechanical trauma without infection playing any recognized part. Deft and gentle manipulations should be the rule, and lacerating and puncturing instruments should have no place in pelvic surgery. For general manipulation of the pelvic viscera other than the uterus, the safest and best instrument is the ring sponge holder with the blades protected by a piece of rubber tubing. It can be used with impunity to handle the intestines, the Fallopian tubes, the ligaments, or the peritoneal reflections. Operations of expediency for the correction of mechanical defects should at least afford a reasonable guarantee against postoperative evil consequences, and one should use some method which will not cause any intrapelvic damage. In any case, care must be exercised to strip back the peritoneal reflections thoroughly onto the ligament, so that the patient will not have the nerve-racking dragging sensation so often felt when the peritoneum has been pulled into the abdominal wall. The ligamentary loops should be given sure anchorage and be smoothly disposed of beneath the aponeurosis of the external oblique.

6. How to Fit Up a Laboratory for £10. H. W. Crowe.

1. **Early Functional Treatment in Contusions and Sprains of the Back.**—F. Shufflebotham emphasizes the importance of early functional treatment in cases of contusions and sprains of the back, stating that this form of accident has been neglected by medical men. In all injuries to this region it is essential to eliminate fractures of the spine, which in some instances can be diagnosed only by means of the *x*-rays. A sprain of the back is, as a rule, a complicated injury which may involve muscles and nerves, as well as the joints of the vertebral column, and a knowledge of the anatomy of the lumbar region is essential before the nature of the sprain can be properly understood. These cases are thought lightly of at the time of the accident because, in the majority of cases, the only symptom is localized pain; but they should receive the same attention as fractures and dislocations because of the long-continued disability from work, to say nothing of the pain and suffering which ensue when the treatment is neglected. The author alludes to the urgency of massage and systematic exercises being prescribed early in these cases so as to avoid the formation of adhesions and the atrophy of muscles, and states that the subject is of the utmost importance in industrial districts because of the great frequency of these injuries.

2. **Epithelial Grafting After the Complete Mastoid Operation.**—C. A. Ballance points out that the advantages gained by grafting the mastoid cavity are as follows: (1) Rapid healing of the entire wound, bone, cartilage, and soft parts, on ordinary surgical principles. (2) Immediate protection of the raw bone surface by a layer of living epithelium, and, in consequence, elimination of the pain and discomfort otherwise incidental to treatment by tamponing and of the liability to reinfection of the bone. (3) Considerable shortening of the time during which specially skilled attendance is necessary. Two weeks after the grafting operation the bone granulations are all covered by visible living epithelium, and the rest of the attendance may safely be left to the family doctor. (4) Improvement in hearing. When the graft has been cut very thin and successfully applied healing takes place at once under the best conditions. The graft, except its inner layer of living cells, separates by asceptic molecular necrosis. The fenestræ become covered by the thinnest possible layer of tissue, and consequently the hearing is generally very good, and is certainly much better than when granulation has long been present over the fenestræ. The above advantages are almost invariably obtained when all bone disease has been removed and the raw bone surface has been covered with a single graft, cut sufficiently thin, and accurately applied.

3. **Operative Treatment of Fractures in Children.**—H. H. Sampson concludes that the treatment of simple fracture by open operation gives more perfect results than can be obtained by any other method at present in general use. With reasonable care the dangers of such treatment are negligible. The mortality has been *nil*, and no instance of wound infection has occurred in a complete series of cases. The insertion of a metal plate gives no trouble after a clean operation. Operative treatment should be applied to recent fractures, and not reserved for the imperfect results of conservative measures. The chance of a perfect result being obtained is diminished by the length of the period which elapses between the accident and the operation. Rarefying osteitis and sinus formation do not occur aftr a clean operation. In view of these results it is reasonable to urge the more extended adoption of Lane's methods for the treatment of simple fractures.

5. **Appendicitis as a Result of Blood Infection.**—F. J. Poynton and A. Paine report their recent supplementary investigation on this subject which they believe brings one a step forward in the study of the etiology of appendicitis. Since Kelynack in 1893 directed attention to the relation of tonsillar inflammation to appendicitis many German investigators have devoted much attention to the point. The authors' earlier paper showed that in young rabbits a micrococcus which they look upon as the exciting cause of acute rheumatism could produce a local lesion in the appendix by direct blood infection, and bearing in mind the importance of tonsillar inflammation in rheumatism those results naturally strengthened the view put forward by Kelynack.. The recent investigation apparently showed beyond reasonable doubt that the diplococcus in the tonsil and in the sanious fluid from the appendix in the authors' case were identical in nature and the cause of the lesions in the human throat and appendix and also of those in the appendix and joints of the experimental rabbits. In other words, they seemed to prove almost conclusively that a cause of appendicitis may be a streptococcal invasion through the blood stream from a follicular tonsillitis.

6. A Scheme for Medical Benefit. L. J. Picton.
7. The Reform of Hospital Out-patient Departments. A. Stanley Parkinson.

1. **Spinal Anesthesia by Stovaine.**—F. C. Madden and H. Shaheen believe that stovaine is a reliable anesthetic for all operations below the costal margins, but one must not expect too much of it, or employ it without careful consideration, especially in cases in which any form of general anesthetic would be dangerous. Moreover, the fallacy that after the injection is given and anesthesia is established it is no longer necessary to trouble about the patient, must be once and for all dismissed. Just as much care must be exercised in the administration of the drug and in the management of the patient after injection as with chloroform, and when this is done the feeling of satisfaction after an extensive operation under this form of anesthesia, when the stovaine has acted perfectly and the after-effects have been almost *nil*, must be experienced to be thoroughly appreciated.

2. **Complications Following the Administration of Hedonal.**—R. A. Veale alludes to the more extended use of the intravenous injection of hedonal as a means of inducing general anesthesia. In 300 cases in which this method was followed in the Leeds General Infirmary, the following complications resulting from the use of this method were recorded as follows: Cutaneous edemas, chiefly in the lumbar and gluteal regions; blisters, most commonly found on the heels or outer side of the foot; pulmonary edema; pneumonia; infarction of the lungs; venous thrombosis either at the site of injection or in the femoral vein; and cerebral thrombosis.

3. **Local Application of Salvarsan in the Treatment of Chronic Superficial Glossitis.**—A. A. Allport used one and a half grains of salvarsan dissolved in one-half ounce of glycerin, of which quantity only about a half was used in hourly swabbings over ten hours in the treatment of a case of chronic superficial glossitis. The author emphasizes the following points that this case presented: (1) The long standing of the glossitis and the rapid proliferation of the ulcer which had been formed by the removal of the nodule. (2) The condition of the tongue

became more acute and painful under the administration of iodide and mercury, although the patient had given up all tobacco for over two months. (3) The patient had been under careful medical treatment on and off for seven years before the author saw him, and had given up smoking for short periods. He had improved under these treatments temporarily, but his own confident assertion was that his tongue had never been so comfortable or looked so well for ten years as at the present time. (4) The extraordinary rapidity of the improvement of the whole tongue. At the end of one week, and after only two days of salvarsan the ulcers had diminished to one-quarter their size. There may possibly be a field for similar treatment of chronic inflammations of the nose as well as the mouth, such as old-standing antrum trouble, and it would be useful to hear the opinion of bacteriologists on this subject.

Berliner klinische Wochenschrift.

August 12, 1912.

Thyroid Metastases in Bone.—Regensburger speaks of the special interest attached to this subject. Clinically and for the most part anatomically as well these growths impose themselves as ordinary sarcomata of the bones, and not until the microscopic diagnosis is their full import realized, for they show a far-reaching agreement with the structure of the thyroid and of goiter. The thyroid in such cases may or may not be the seat of malignancy. The author has found in literature notes of 59 cases of this kind of metastasis. The exact nature of the process is far from being settled and the character of the growth has been pronounced benign (at the outset) and malignant, and the parent formation has been called simple goiter, malignant adenoma, and carcinoma. It seems agreed that it has no connection with sarcoma. The author proposes thyreogenic tumor as a designation sufficiently accurate and comprehensive. Clinically there should be no confusion between this affection and struma maligna, for the latter, in addition to causing metastases invades its neighborhood and gives use to numerous pressure symptoms. As a rule, what has seemed to be a harmless goiter suddenly takes on acute symptoms. The converse happens in thyreogenous tumors where the course of the affection is measured in years and not in months. Struma maligna is one of the most rapidly fatal types of malignancy, thyreogenic tumor one of the most deliberate. The arrangement of the metastases is also very dissimilar in the two affections, although in both there is a notable tendency to involve the bones, which in the thyreogenic tumors is characteristic of the disease. In struma maligna the percentage of bone metastases is over 24, these being second in frequency only to the pulmonary metastases. Hence there is some close connection between the thyroid and the bones, as also seen in cretinism.

Phonoscopic Percussion.—Tornai mentions the strong individualization of the results in ordinary percussion which stand much in the way of harmonious consultations. Something is required to lend more objectivity. He then refers to the orthopercussion method, so-called, of Goldscheider, Moritz, and Dietlen, in which attempts are made to create vibrations through the chest which are capable of being registered or of causing sounds which may be overheard. No reference is made to the ordinary auscultatory percussion of textbooks. It is essential that percussion should be very gentle. The author also uses two separate stethoscopes, which when employed in combination he terms the phonoscope. For a pleximeter he uses his left forefinger. The percussion movements of the right middle finger should be made rapidly—three or four a second. This method was discovered entirely by chance, for he was engaged in orthopercussion while the stethoscope (a double one, for he had been making studies of the heart cycle) hung loosely from the ears. The sounds of percussion he found were rendered much more distinct, apparently as a result of the projection of the vibrations through the surrounding media. The vibrations should proceed from the smallest possible area.

Distention Luxation in Syringomyelia.—Joachimsthal the orthopedist reports a case of dislocation of the first row of phalanges on the metacarpals which proved to have been due to alterations of the joints the result of syringomyelia. As is well known, the latter disease causes extensive trophic alterations in the upper extremities, as does tabes dorsalis in the lower limbs. The arthropathies which result bear a certain resemblance to arthritis deformans, with this difference that in the former class the analgesia contributes to aggravate the state of affairs. In the neuropathic arthropathies we usually see destruction of the articulating structures, but the dislocations may exceptionally occur without this prerequisite, especially in the shoulder joints. It is indeed strongly probable that some cases of habitual dislocation of the shoulder joints are due to syringomyelia. In many cases of dislocation at the elbow, wrist, and fingers radiography has shown extensive destruction of the articular surfaces. In the author's case, however, the latter are seen to be quite intact; so that the changes which made possible the dislocation must have resided in the capsule of the joints. The displaced bones could be readily restored and held in position and the dislocation was probably attributable to distention of the joints as a result of the spinal malady.

Münchener medizinische Wochenschrift.

August 13, 1912.

The Portable Museum of Nursling Care of Bavaria.—Koebner describes this institution, the first of its kind in Germany, and the idea of Professor Hecker, first put into practice in 1910. The first exhibit comprises data on nursling mortality, which naturally furnishes the *raison d'etre* of the museum. This is made as full and comparative as possible, the records going back to 1862. The effects upon the mortality curves of breast feeding are brought out in unmistakable fashion. Natural feeding is taught by showing the right and wrong positions, by properly constructed and ill constructed teething rings, nipples, etc. To forbid these devices is not deemed prudent. Analyses of milk at different months show the fallacy of the claim that women run out of supply at untimely periods. Naturally the possibilites for illustrating artificial feeding are very much greater. Certain bottles show the limits for feeding portions. The warmth of the bottle is tested by holding it against the eyelid, not by tasting (shown by two designs). Clothing and care are illustrated by models. Bathing, taking the rectal temperature, care of vaccination pustule, and other details are illustrated. The physiology of the nursling is illustrated in many ways. The food requirements are given. The caloric energy is shown in amounts of coal, so that it readily appears that the greatest demand for fuel is in the third month. Tables of weights, lengths, and ages are given. Photograph albums showing the nursling conservation movement in all its phases as carried out in the city of Munich complete the museum.

Sexual Pedagogy.—Grassmann gives a summary on this subject based on the work done and facts learned, with reference to Munich. The precosity of intercourse and of the sexual impulse, among the boys at least, has led to an increase of venereal diseases, perhaps also of masturbation. This can be antagonized only by education which inculcates a sense of chivalry toward girls, a consciousness of social duties and obligations, and a strong will as part of a physical training, and provides a full explanation of sexual matters to rob them of any mystery, etc. This education must be personal and individual and

undertaken by parents and the family physician. Class instruction in schools must also deal with these problems. Degenerate children should be kept out of the grades and in special classes.

The Eucalyptus Treatment of Scarlatina and Measles.—Kretschmer states that this treatment did not originate with Milne as is erroneously believed. It was taught as far back as 1890 by Curgenven, who used eucalyptol both externally and internally and even as a common disinfectant of apparatus and bedding. The author has used the treatment extensively in Strassburg according to the directions of Milne, and cannot endorse it as preventing complications. In 77 cases of scarlatina there were complications in one-half of the patients. In not a few cases these supervened after the completion of the treatment. In a control series of cases before the treatment was adopted there were fewer complications.

Deutsche medizinische Wochenschrift.

August 15, 1912.

Treatment of Arteriosclerosis.—Hochhaus mentions the frequent inherited tendency to this affection and also its dependence on a number of individual factors. The earliest symptoms often appear when it is too late to arrest the disease. All the possible causal moments must be eliminated one after another, as the excessive use of alcohol, tobacco, and coffee. Physical or mental overeffort must be offset by rest, work being restricted in duration and intensity. The ideal state to be attained is one of quiet activity. The patients are naturally excitable and this should not be aggravated by worry or foreboding. The question of diet is a vexed one and the best course is to avoid any kind of extremes. This applies also to the ingestion of fluids. As a rule, this should amount to 1,500 c.c. As for drugs, there are no specifics, but iodine approximates one. It unburdens the circulation in some unknown manner. Nothing is gained by giving large doses. The value of the nitrites and nitrates is questionable because they are not really indicated. The author does not believe that it is necessary to lower the blood pressure save on special occasions. The balance of the treatment is chiefly hygienic, comprising hydrotherapy, massage, etc. Many indications are not due to the disease *per se*, but to its complications, as nephritis. The high-tension current is not even mentioned.

Statistics of 367 Choledochotomies.—Brüning concludes from this large material as follows: No opportune operation, an appedectomy, for example, should be done on the occasion of a choledochotomy. The hepatic duct should always be drained and in addition to the catheter a drain and tampon should be used as protection from escaping bile. One should irrigate constantly in the after treatment. In cholangitis one should keep up drainage for months, for even the escape of sterile bile does not protect against recurrence. As cystotomy often causes subsequent pain the prospect of an ectomy should always be considered. If one can feel distinctly an indurated pancreas an anastomosis should be made. In respect to opening the choledochus this should be done whenever stones can be felt or when we know they have escaped; when the duct is dilated or there is a suspicion of cholangitis; when bladder with cystic duct patent contains small stones; when the bile—the excretory duct being patent—is turbid or purulent. The author's total mortality for his series was 7.7 per cent. and this can only be bettered by earliest possible intervention.

Food Poisoning Simulating a Cerebral Focal Affection.—Meyer refers to the close association between intestinal autointoxication and cerebral symptoms, especially in children. Heubner mentions a "coma dyspepticum." In the first three years of life such conditions are encountered which are not cyclical nor connected with acetonuria, and which present great diagnostic difficulties. The fatal convulsions due to gastroenteric disturbance naturally suggest themselves here, and many lives might doubtless have been saved if the treatment had comprised rapid evacuation of the elementary canal. The author cites a case in point: A child aged 3 years fell ill suddenly with convulsions, unconsciousness and fever. The medical attendant erroneously prescribed purely symptomatic treatment, chloral and cold packs, but fortunately the former was not administered (it was to be used contingently). The parents of their own accord had given castor oil which brought away much foul smelling fecal matter. The author found the child in a sort of tetanoid rigidity. There had been no ingestion of questionable food, save perhaps of slot-machine candy, but something eaten the day before had evidently disagreed, for the irregularity of the picture suggested a food poisoning. The cerebral symptoms persisted three or four days, and throughout there were choreic movements on the left side which suggested a focal lesion in the right hemisphere. During this period the child was unconscious and out of its head when roused. To explain the picture it was necessary to assume the existence of a focal encephalitis or meningitis due to some toxic intestinal product. The latter was unknown. Of the various articles eaten, all of which were part of the regular diet, sourkrout may have been the offending substance. Whatever may have been at fault the case harmonizes well with ptomaine poisoning resulting from stagnation.

Epilepsy of Cardiac Origin.—F. Mouisset and J. Gaté state that in the course of a prolonged and persistent asystole the alterations in the circulation of blood in the brain, the presence of toxic substances, and the vascular and inflammatory lesions in the brain combine to produce a hyperexcitability of the latter organ. This may express itself in crises of true epilepsy or of related psychic manifestations.—*Revue de Médecine.*

Tonic Spasm of the Muscles, Chiefly of the Extremities (? Myotonia).—J. Galloway reports the case of a girl, aged fourteen, who is said to have shown no signs of the present condition of the muscles of the left arm and leg till about Christmas, 1911. She states that she could play the piano readily up to that time. It was then noted that she had difficulty in moving the muscles of the left arm and hand, a condition that has continued and increased up to the present time. There is similar difficulty in moving the muscles of the left leg and foot. The right arm, hand, and leg appear to move practically normally. On observing the muscles of the left arm and hand they are found to pass into a condition of spasmodic contraction on very slight exertion or stimulation; the contractions resulting relax very slowly. On clasping the hand on any object the grasp of the hand continues for a considerable period of time—many seconds—and it is only after strong voluntary effort or after waiting for some time that the grasp is relaxed. Movements bring about a similar long-lasting spasm of the muscles of the left shoulder. Similar long-enduring spasm affects the muscles of the left leg and foot, causing some impairment of ease in walking. The toes become spread out in a spasmodic manner on attempting to extend the foot, and the calf muscles, as also the extensors of the leg, become firm and remain so for an unusually long time. All movements become easier and more rapidly executed when repeated. The electrical reactions are normal, there is no alteration in sensations, and no definite evidence of increase of reflexes, nor are there involuntary muscular movements. The child is well in all other respects. There is no evidence or history of injury to the head or brain, no headache, vomiting, or sickness, the eye movements are normal, and there are no changes in the fundus oculi. The character of the movements of the muscles suggests "myotonia." It is noteworthy that this condition is stated to have commenced about five months ago, and that no history is obtained of any other member of the family being affected in this way. The affection of the muscles is almost entirely limited to the left side, chiefly the arm and leg. The condition of spasm, although markedly increased on voluntary movement, is probably never entirely absent, and there is a slight suspicion of increase of the tendon reflexes of the lower extremity.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS

BY THE INSURANCE EDITOR.

THE URINE.

THE chemical examination of the urine is a mechanical process and there is no justification for inaccuracies, especially as the examiner is not asked to make a scientifically complete uranalysis for the discovery of small abnormalities as an increase or decrease in the phosphates, chlorides, urea, or uric acid, the practical significance of which is usually not definitely known. In fulfilling the requirements that are called for, however, the companies expect the examiners to use the utmost care and precision, as otherwise the analysis will be valueless. The standard methods described in the following lines are simple and reliable, and there will be no danger of the occurrence of mistakes if they are faithfully followed.

Urination.—Symptoms of disease of the urinary organs, such as frequent or painful micturition, persistently turbid or otherwise abnormal urine, should be carefully investigated.

When the applicant acknowledges to urinating at night, it is essential to learn the frequency, amount passed, and the reason. In men over 50 it may be due to prostatic disease. On the other hand, it may be occasioned by drinking considerable water or some other beverage before retiring or may be due merely to habit. Close questioning will usually elicit the desired information.

How to Procure Urine.—The urine must be voided in the presence of the examiner. When, however, the applicant is a woman, the examiner must be near enough to be morally certain that the urine is passed by the applicant. He should also notice whether the urine, when returned to him, is in the container presented by him to the woman for that purpose and is still warm. A report must never be based upon the analysis of a specimen which has been brought or sent to the examiner.

How to Report Abnormal Ingredients.—If the first specimen presents an abnormality, either in specific gravity or by the presence of albumin or sugar, the examiner should obtain and analyze a second specimen before reporting; then if the second specimen also presents the abnormality, he should include the analysis of both specimens in the medical report and forward it to the home office in the usual way. If, however, the second specimen presents no abnormality, a third specimen should be obtained by the examiner and sent to the home office properly preserved and vouched for, the analysis of the first and second specimens being included in the examination report. In addition to this, the medical department will usually call for still another sample to be mailed to the home office in a container which should be sent to the examiner and which carries in it an antiseptic to act as a preservative.

In all instances when albumin or sugar has been found in the urine, a statement signed by the applicant as to whether or not he has been under treatment or on restricted diet for albuminuria or glycosuria during the past six months, should be furnished if the examiner finally decides to recommend the risk.

These requirements are practically the same in all companies, though there may be an occasional slight variation

APPARATUS.—The only apparatus needed is:

1. Two test tubes, five or six inches long and one-half to three-quarters of an inch in diameter.
2. Urinometer of a reliable make, preferably Squibbs. Test it frequently in distilled water; if it rests at the zero mark it may be considered accurate.
3. Alcohol lamp or Bunsen burner. The latter is always ready and a time saver.
4. Litmus paper, red and blue, of a reliable make. This should be kept in bottles so that it will not be affected by volatile acids and alkalies.
5. Glass pipettes.
6. Filter paper and a glass funnel.

The only reagents needed are:

1. Nitric acid, chemically pure.
2. Strong official acetic acid.
3. A solution for testing sugar.

(The subject of uranalysis will be continued in succeeding numbers.)

Research Work in Life Insurance Medicine.—By Frederick L. Hoffman. (See page 417.)

A Trace of Albumin.—According to W. Blair Stewart a trace of albumin in the urine is the red flag of danger, and it is the duty of the insurance examiner on the one hand to give the company every benefit of doubt—and on the other to recognize the personal rights of the individual examined. After definitely deciding that albumin is present in very small trace, it is just to the company and patient to examine at least three specimens taken at different times of day before final report is given. Physiological and functional albuminuria must be distinguished one from the other with care. More injustice is done to women applicants than to any others and the fact must be taken into consideration that a menstrual flow in small amounts is likely to deceive the examiner unless he be careful. The sphygmomanometer should be used in every albumin case, as the presence of albumin in trace with a high blood pressure is almost invariably an indication of organic kidney disease. Every albumin case should be held up and studied as not suitable for insurance until such time as it can be declared free from disease or trace of albumin. The foresight of those companies that have established a system of periodic health examination of their policy holders should prove a great economic factor in preventing and eradicating diseases that have been developed in the first examination or that have developed since.—*The Lancet-Clinic*, July 27, 1912.

German Invalid Insurance.—The number of cases of sickness with inability to work which received aid from the various classes of invalid insurance in Germany during 1910 was 5,197,080 as against 5,045,793 in 1909. The average number of members increased from 12,519,785 in 1909 to 13,069,375 in 1910. The total number of days of sickness for which compensation or hospital treatment was given was 104,708,794, an average of 8.03 per member, compared with 103,368,112 days in 1909, an average of 8.26 per member. The total number of funds was 23,188 in 1910, divided among parish invalid insurance, district sick funds, trade funds, building funds, corporation funds, and registered funds. The joint capital of the various funds amounted to $70,543,240 in 1910 and the receipts minus those for invalid insurance came to $90,269,710. The regular expenses minus the cost of management for invalid insurance amounted to $83,429,752. The costs of illness included in the last total aggregated $76,164,937.

Book Reviews.

Recent Methods in the Diagnosis and Treatment of Syphilis (The Wassermann Serum Reaction and Ehrlich's Salvarsan). By Carl H. Browning, M.D., Lecturer in Clinical Pathology, University of Glasgow; Director Clinical Research Laboratory, Western Infirmary, Glasgow; and Ivy McKenzie, M.A., B.Sc., M.B., Ch.B., Director Western Asylums' Research Institute, Glasgow; Physician to the Out-Patient Department, Western Infirmary, Glasgow. In collaboration with John Cruickshank, M.B., Ch.B., and Charles G. A. Chrislett, M.B., Ch.B., Walter Gilmour, M.B., Ch.B., Hugh Morton, M.B., Ch.B. With an introduction by Robert Muir, M.A., M.D., F.R.S., Professor of Pathology in the University of Glasgow. Price, $2.50. Philadelphia and New York: Lea & Febiger, 1912.

Those persons who assumed a critical attitude toward the theoretical basis of the Wassermann reaction when it began to come into use in 1907 have now received their final justification in the report by Noguchi that extracts from pure cultures of the *Spirocheta pallida* do not act as antigen in the Wassermann reaction. This means either that the Wassermann reaction is absolutely non-specific or that the *Spirocheta pallida* is not the cause of syphilis. The first is probably the true statement of the conditions. As soon as it was shown that oleic acid, soap, and extract of rabbit's heart could be substituted for syphilitic tissues in carrying out the Wassermann reaction, it was evident that the syphilitic poison merely produces some change in the fatty and lipoid constituents of the blood which gives a complement fixation under certain conditions. There is no reason, therefore, except a statistical one, for the reaction having any diagnostic value. At the present time, however, there is such a large body of statistics showing the real diagnostic value of the Wassermann complement fixation test that the establishment of its final usefulness seems undoubted. It is largely by the work of such men as the authors of this very valuable text that the final determination of the question has been reached. The practising physician without laboratory training who attempts to read it will certainly learn a good deal; he will also in all probability not understand a considerable part of it; but any one who is familiar with the recent laboratory works on immunity and especially that portion directed toward the diagnosis of syphilis will find in the volume the answers to many questions, an explanation of much of the complicated matter now seen in current medical journals, and a good example of the amount of painstaking work which is required to produce what may seem to be a very small yield of practical value. It is impossible within the limits of a review to discuss all the points treated; it can be said only that the technique of the various modifications of the Wassermann is given very fully, as well as the methods of making antigen, the theory of the reaction, its clinical application, and a study of the cerebrospinal fluid. In the second part there is a very full study, both from the authors' own experiences and from the reports of published cases, of the effects, curative and fatal, of the administration of salvarsan. The work is a very valuable contribution to the literature of syphilis.

On the Physiology of the Semicircular Canals and Their Relation to Seasickness. By Joseph Byrne, A.M., M.D., LL.B. New York: J. T. Dougherty; London: H. K. Lewis, 1912

The writer of this book says in his preface that he makes no pretensions of priority in time respecting the experimental production of phenomena resembling those of seasickness; but he claims that his experiments were made before he had any information of the work done by Bárány, Neumann and the others who have worked along their lines. We find no reference to Bárány or Neumann in the list of 288 names in the bibliography. The writer's experiments, he says, were undertaken from a belief that the semicircular canals were involved in the causation of seasickness. He used rotations, aural irrigations, stimulation of the retina by strong light and galvanism to the mastoid areas. The phenomena of nystagmus and the displacements of the head that occur in rotations, aural irrigations, etc., and the mechanisms involved in their production are studied and carefully worked out. The sickness induced experimentally, in ways stated above, is compared with seasickness elaborately studied in a number of cases on board ship. The effects upon the organism as a whole and upon the mechanisms of digestion and of the circulation were found to be analogous. A condition of hypoacidity of the stomach was found in both instances. Vasomotor exhaustion is an important feature. Most drugs and alcoholic stimulants are contraindicated. Atropine and strychnine were found useful for the subjective sensations. The book is extremely interesting and a valuable contribution to the subject.

Ophthalmic Myology. A Systematic Treatise on the Ocular Muscles by G. C. Savage, M.D., Professor of Ophthalmology (Defects of the Eye) in the Medical Department of Vanderbilt University, Author of "New Truths in Ophthalmology" and "Ophthalmic Neuro-Myology," ex-President of the Nashville Academy of Medicine, ex-President of the Tennessee State Medical Association, ex-President of the Southern Medical Association. Eighty-four illustrative cuts and six plates. Second edition. Published by the Author, Nashville, Tenn., 1911.

The fact that Dr. Savage's work is now in its second edition attests to the interest that it has awakened. In his study of physiological optics he arrives at conclusions differing from those that were enunciated by Helmholtz and that have since ruled: 1st. In relation to the location of the anterior and posterior poles of the eye. 2d. The place of crossing of the secondary visual lines in the eyeball. On the conclusions that he has arrived at Dr. Savage proceeds to construct the phenomena of optics as presented in the human eye. The ocular rotations are carefully and exhaustively considered. The innervation of ocular muscles to maintain binocular vision throughout the "field of binocular fixation" is explained by the construction of quite an elaborate scheme of "innervative centers" the existence of which is asserted with much positiveness and the location of which is conjectured. The horopter or isogonal circle is described to the author's satisfaction on the hypothesis of the physical and anatomical conditions believed by him to exist. Laws of binocular rest and motion are laid down. Methods of testing and ascertaining the condition of ocular movements are described, together with the various operative and non-operative procedures for the correction of errors The work is one of 685 pages, is well printed and well illustrated. The subject as presented by Dr. Savage is deserving of the careful study of those interested. While the majority of the students of ophthalmology are not inclined to indorse Dr. Savage's position there is much in the work that is worthy of consideration.

Studien über Darmträgheit (Stuhlverstopfung), ihre Folgen und ihre Behandlung. Von Dr. Franz Xav. Mayr, in Karsbad-Wien. Price 6 marks. Berlin: S. Karger, 1912.

Dr. Mayr gives the usual causes and varieties of constipation and then attempts to analyze its consequences, both local in the gastrointestinal tract and indirect as shown elsewhere in the organism. In gathering the various injuries caused by constipation he has not seen fit to exclude such hardly probable conditions as diseases of the liver, tumors, etc. On the other hand, he gives a moderate picture of "autointoxication," and is especially clear, simple and sane in his therapeutic directions. The book contains much that is original and should prove of value to the internist.

The Tobacco Habit: Its History and Pathology. A Study in Birth-Rates. Smokers compared with Non-Smokers. By Herbert H. Tideswell, Member of the Royal College of Surgeons, England; Licentiate of the Royal College of Physicians, London; Late House Surgeon to St. George's Hospital and Northampton Infirmary. An Appeal to Medical Students and all Members of the Medical Profession who are true Christians and zealous in promoting true Hygiene and Temperance. Price, $1.40. London: J. & A. Churchill, 1912.

Not since good King James issued his famous counterblast against tobacco has there been so serious a charge brought against the use of this comforting weed. At the very outset the author puts his finger upon the difficulties of his task in his statement that: "Unfortunately a very serious drawback to any crusade against smoking is its very wide prevalence among medical men who ought to know and hence act better." After reading this volume it is impossible that any sane man could ever smoke again. The author proves, to his own satisfaction at least, that the use of tobacco causes weakening of the mind, cardiac irregularity, malingering in the British Navy, and impotence. Smoking in the husband even causes miscarriage in the wife and imbecility in the children, and an excess of female children over male is also a definite sequence of the intemperate use of tobacco. Epileptic convulsions and fatty degeneration of the arteries are further sequelæ, and it is to be regretted that space is wanting to complete the list of serious conditions due to tobacco smoking. All "antis" will find both comfort and ammunition in this book.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-fourth Annual Meeting, Held in Atlantic City, N. J., May 9, 10, and 11, 1912.

JAMES E. NEWCOMB, M.D., PRESIDENT, IN THE CHAIR.

The Exenteration of the Ethmoidal Labyrinth by the Intranasal Route.—Dr. HARRIS PEYTON MOSHER of Boston read this paper, stating that the anterior boundary of the ethmoidal labyrinth was made by the internal angular process of the frontal bone and the posterior surface of the ascending process of the superior maxilla. The labyrinth could not be entered effectively unless the curette were carried outward behind the ascending process of the superior maxilla toward the lacrymal bone. Removing the anterior end of the middle turbinate and curetting upward and not outward did not open the labyrinth to any extent. The internal angular process of the frontal bone made two-thirds or the whole of the bony ring which was the first part of the nasofrontal duct. The best guide to the duct was the posterior surface of the ascending process of the superior maxilla. In a large number of cases the nasofrontal duct was not a tubular canal, but consisted of a bony ring at the beginning and then became a triangular anteroposterior slit. This was more like an ethmoidal cell or an irregular meatus than a duct. The nasofrontal duct tended to run from without inward and to come into relationship with the extreme upper part of the anterior end of the middle turbinate. When the drainage canal of the frontal sinus had the cell-form the anterior end of the middle turbinate made its inner boundary. The duct, therefore, was reached most easily through the nose and through the anterior end of the middle turbinate at the level of the superior turbinate. A curette introduced at this point and carried outward toward the lacrymal bone and then withdrawn a little and carried straight downward and backward entered the anterior part of the labyrinth behind the ascending process of the superior maxilla and broke down the cells through which the nasofrontal duct ran, destroying both the cells and the duct. Very little curetting was required to convert the anterior part of the labyrinth into a single cavity. In the roof of this chamber, usually in the anterior outer angle, the opening of the nasofrontal duct was placed. If it was the wish of the operator to clean out all the ethmoidal cells the posterior half of the labyrinth was entered by piercing the attachment of the middle turbinate and by curetting still further backward, using all the while the outer side of the middle turbinate as a guide. If the head of the patient was held level the middle turbinate guided the curette backward into the posterior ethmoidal cell. Often the posterior half of the labyrinth was a large cavity made up of only one or two cells. This portion of the labyrinth had been, as it were, exenterated by nature. When the curette brought up against the back wall of the labyrinth the remaining part of the middle turbinate and the lower half of the superior turbinate were removed. Then the posterior part of the superior turbinate was taken away flush with the front face of the sphenoidal sinus. The operator now recognized the inner part of the front face of the sphenoidal sinus which is free in the nasal cavity, and the outer part which had a common wall with the posterior ethmoidal cell. The upper outer angle of the posterior ethmoidal cell was dangerous to curette or to probe. It was of the utmost importance that the operator should be sure of his landmarks in this locality. He orientated himself by finding the upper rim of the choana and then differentiating the free face of the sphenoidal sinus by probing upward from the rim of the choana close to the septum. Having made out the extent of the free face of the sinus the width of the common wall between the sphenoidal sinus and the posterior ethmoidal cell was determined. The dividing line between the two parts of the anterior face of the sphenoidal sinus was made by an obliquely vertical line which was the attachment of the superior turbinate. A common mistake made by the operator was to get lost in the posterior ethmoidal cell—he went too high and too far outward and considered the posterior wall of the posterior ethmoidal cell as the whole of the front face of the sphenoidal sinus. This mistake, if persisted in, would carry him into the brain. Insufficient removal of the posterior part of the superior turbinate and allowing the head of the patient to become tipped upward, were the chief causes which led to this confusion. After the landmarks of the front face of the sphenoidal sinus had been cleared and recognized the sinus was entered near the septum, if possible through the ostium, and the whole of the anterior wall removed. The mishaps of the operation were entering the orbit through the lacrymal bone and entering the posterior part of the anterior fossa of the cranial cavity at the apex of the orbit. The first accident was trivial, the second fatal. Puncture of the extreme upper part of the anterior end of the middle turbinate for catheterizing the frontal sinus or for exenteration of the anterior ethmoidal cells was readily accomplished under cocaine anesthesia. For the complete removal of the anterior and posterior cells, especially if this was to be accomplished at one sitting, it was more satisfactory to use a general anesthetic.

Report of a Case of Myofibroma of the Nasopharynx.—Dr. JOSEPH H. BRYAN of Washington, D. C., said the report of this case was interesting from the fact that benign growths of this character in the nasopharynx in children were not very common. Maggie C., an undeveloped and anemic girl, 12 years of age, came under his observation during March of this year, complaining of occlusion of both sides of the nose, headache, noisy respiration, and at times difficulty in swallowing. Examination of the nose showed the left side quite free, but no air could be drawn through it into the nasopharynx. The right side was so filled with thick mucus secretion that no satisfactory view of the interior could be obtained. After clearing the nose of mucus he could not get any view of the growth. Examination of the mouth showed a large pinkish growth hanging in and filling the nasopharynx almost completely. The growth extended into the pharynx about 1/6 of an inch below the free margin of the soft palate. Owing to the great timidity of the child it was impossible to remove the growth without the aid of a general anesthetic, so she was placed under ether anesthesia, and a wire snare was passed well up into the nasopharynx, the growth seized, and after firm traction withdrawn. The hemorrhage following was quite severe for a few moments, but gradually subsided after firm compression by means of a gauze compress passed well up into the nasopharynx. The growth after removal was found to be pinkish in color, quite firm to the touch, and measured 3 inches in length. Several days after its removal, on posterior rhinoscopic examination, an excellent view of the nasopharynx was obtained, and there were two points which showed an ecchymotic state, either of which might have been the seat of attachment: one in the roof of the nasopharynx which contained some adenoid tissue, and the other in the right posterior nares just above the posterior extremity of the middle turbinal. The latter was probably the point of attachment. The following was a report of the microscopic examination made by Dr. J. B. Nichols: "The tumor is covered with stratified columnar epithelium, and is made up of myxofibromatous and soft fibromatous tissue, containing massive extravasations of blood and fibrin, small blood vessels are plentiful, gland structure nearly absent. Scattered through the substance of the tumor, in places in more or less dense collections, are an abundance of polymorphonuclear leucocytes, small lymphocytes, plasma cells, and pigmented phagocytes." It was impossible to estimate the frequency with which these neoplasms occurred, owing to the fact that many cases were not reported, but judging from the number of reported cases they could not be considered to be very common. Myxofibromas might be considered of nasal origin and generally sprang from the upper part of the posterior nares, where the nasal mucous membrane was continuous with that lining the nasopharynx, while fibroma, a much more serious affection, had its origin in the nasopharynx. The former might therefore be said to partake of the characteristics of both nasal and nasopharyngeal growths, which might be explained by the fact that they sprang from the junction of the two cavities, the lining membrane of the two cavities being quite distinct histologically.

Report of a Case of Rhinopharyngeal Fibroma.—Dr. JOSEPH S. GIBB of Philadelphia reported this case of a boy 13 years old, having symptoms of nasal obstruction for six months with epistaxis. Examination showed growth springing from vault, probably from basillar process, everywhere attached, and covered by mucous membrane. No pedicle. Ether was administered, and a preliminary tracheotomy performed. An effort was made to remove the growth by heavy wire snare passed through the nasal chamber, but entirely unsuccessfully. The growth was then grasped by strong postnasal forceps and by a tearing, twisting and traction movement, combined with an effort to separate the growth from its attachments by the index finger of the operator's left hand, the growth was finally removed. The bleeding was free during the manipulation and profuse when the growth came away. The vault was packed with gauze; upon its removal there was very little bleeding and it was not replaced. The tracheal tube re-

mained for one day; the recovery was uninterrupted. There had been no recurrence, although more than two years have elapsed since operation. In his remarks on the subject of rhinopharyngeal fibroma Dr. Gibb emphasized the importance of early diagnosis. At this time the growth might be removed either by the hot or cold wire snare or avulsion with comparatively little danger; later, when the growths had attained a larger size, extended into the contiguous cavities, and formed dense adhesions, the difficulties attending removal are greater. In some cases avulsion might be employed, but in the greater number of the advanced cases he believed it better and safer to use a combination of electrolysis, galvanocauterization, and the hot and cold wire snare. One or all of these measures should be used, depending on the character of the case.

Aphthous Ulceration of the Upper Air Passages in Pulmonary Tuberculosis.—Dr. John N. Mackenzie of Baltimore stated that it had long been debated whether the ulceration in question was a specific ulceration due to the special cause of tuberculosis. After a preliminary discussion of the subject the author gave a brief review of the controversy to which it had given rise and recalled in minute detail the description he himself had given of the ulcers and their relation to pumonary tuberculosis which he had published in 1881 in the *Monatsschrift für Ohrenheilkunde* and in the Transactions of the Medical and Chirurgical Faculty of Maryland in the following year (1882). His histological observations went to show that these ulcerated areas were the result of a circumscribed, superficial, "diphtheritic" inflammation of the mucous membrane—that is to say, an infiltration of the tissues with so rich and rapid cell proliferation as to end in necrosis and sloughing of the superficial layers. According to his investigations this form was due to the corrosive action of the sputum from the lung cavities, through the medium of unknown bacteria, and he supported his contention by the following facts: (1) The predilection of the ulcers for those places which were in constant contact with the sputa, viz., the trachea and bronchi, and especially the posterior wall of the former and the laryngeal surface of the epiglottis; (2) the fact that they increased in number as the lungs were approached and that they were much less common in the upper portion of the larynx and trachea; (3) that they might be traced from the bifurcation of the trachea to the division of the bronchial tubes, where in all cases they became visible only in one tube, which was that leading to a cavity; (4) their absence in the bronchi of lungs which were not the seat of cavities or advanced tuberculous change; (5) their occasional presence in the esophagus, stomach, and intestines; (6) their occasional appearance in suppurative pneumonia and gangrene of the lung. He therefore regarded them as an inoculation, so to speak, of the mucosa with the detritus from the broken down pulmonary tissue, leading to a loss of substance pathologically distinct from, but possessing some of the characteristics of, the tuberculous ulcer. Although due to the disintegration in the lung, he did not regard them as specific tuberculous products, for the following reasons: (1) They differed histologically in no respect from similar ulcers found on the mucosa of non-tuberculous subjects; (2) well pronounced circumscribed infiltration due to necrobiosis and sloughing, and identical with these aphthous ulcers, was found, though not as frequently and abundantly in the mucosa, especially of the trachea, as a secondary complication in diseases other than pulmonary tuberculosis (gangrene of the lung, perforation of the trachea by broken down, sloughing bronchial glands); (3) that on other mucous membranes, under similar conditions, namely as the result of a neighboring long-standing gangrenous process, or the constant passage over them of an ichorous discharge, ulceration was found identical with that under review, as, for example, in the vagina as the result of gangrene of the uterus. He concluded therefore that the ulcers were relative to the lung affection insofar as they were produced by the corrosive action of the sputa, but that in the then state of our knowledge they could not be regarded as specific tuberculous products. At the time these observations were made the study of the subject was rendered infinitely more difficult by our scant knowledge of its bacteriology, and the technique of examination then in use was ridiculously primitive when compared with the methods of precision and exactness of modern scientific research. The bacillus had not been isolated and the problem had to be worked out without the light of that discovery. For these reasons it was not surprising that there should have been so much divergence of opinion on the subject. But even with modern methods there was still no consensus of opinion among authorities on the subject (the vast majority of pathologists and laryngologists holding that the aphthous ulcer was a true tuberculous product) until the atmosphere of the question was clarified by the researches of Ziba, in the Pathological Institute at Strassburg. (*Archiv für Laryngologie*, XXIV, Band, Heft, 3, 1911). As the result of his histological and bacteriological researches he arrived at the same conclusions reached by Dr. Mackenzie, and believed with him in the existence of the aphthous, as contradistinguished from the true tuberculous, ulcer of the trachea and larynx, in pulmonary tuberculosis. He had found that it was due to streptococci in the sputa from the lung cavities; that infection took place from the inner surface of the mucosa and produced an inflammatory process associated with tissue necrosis and which led to the formation of the aphthous ulcer; that the latter might become later tuberculous, but in the aphthous ulcer originally there was neither in its base or walls any trace of miliary tubercle. This conception of its nature was furthermore supported by bacteriological examination. Only in the ulcers in which miliary tubercles were discovered were tubercle bacilli found, and solely in the region of the miliary tubercle itself. In all other cases, both miliary tubercle and bacilli were absent. Even in those cases in which tubercle bacilli were found in the secretion which covered the mucosa, both characteristic structure and bacillus were wanting. Aphthous ulcerations of the larynx and trachea produced by streptococci were necessary to or invited the development of tuberculous ulceration. This was all the more probable when it was remembered that they appeared in greatest numbers in the last stages of pulmonary tuberculosis. All this period the great majority of the ulcers were streptomycotic in character and secondary tuberculosis developed in them only here and there.

Indications for the Use of Salvarsan in Syphilis of the Nose and Throat.—Dr. Joseph L. Goodale of Boston stated that his experience extended over 36 cases of syphilis treated by salvarsan. Intravenous injection was done in all cases without stomach disturbance beyond occasional nausea and chilly sensations. The author advised the use of salvarsan in preference to the former methods under the following conditions: First, where prompt removal of infectivity was important on social or conjugal grounds; second, in cases exhibiting tendency to mercurial stomatitis; third, in those patients where lesions continually recurred: fourth, for purposes of diagnosis where it was impossible to remove a specimen for examination, or where prompt control of a supposedly syphilitic lesion was important, as in gumma of the septum: and finally, in those forms of tertiary syphilis which exhibited slow development and a protracted course analogous to the serpiginous gummata of the skin. With reference to the power of salvarsan to effect a cure opinions were not yet unanimous, but the weight of evidence justified the statement that this remedy in repeated doses, and in association with mercury, offered the best hope of attaining this result.

The Upright Position in Ether Operations Upon the Nose, Throat, and Other Portions of the Head.—Dr. Thomas R. French of Brooklyn said that the almost universal fear among surgeons of performing operations upon the nose and throat while the patient was in the upright position had no real foundation in fact. The reasons for preferring the upright position in operating under ether narcosis were many, but the principal ones were: First, better operative work could be done because the surgeon was accustomed to viewing the parts in that position in everyday practice; second, because the field of operation, in the mouth and fauces especially, was better displayed; this largely because the gravity of the soft parts carried the tongue out of the way to a greater degree than in other positions; third, that there was less hemorrhage while the patient was in the upright position; and fourth, that less ether was required after the patient's body had attained the upright position. A new and easy method was demonstrated which had been evolved from that presented to the Association by the writer twelve years ago. With the new method the patient was anesthetized upon, and strapped to, a table, and after the stage of excitement had passed the table top was converted into a chair, and by wheel action the body was brought to the sitting posture. The back of the chair could be lengthened or shortened to fit the back of each patient and also to adjust the head in the headrest for the proper administration of the anesthetic and the desired display of the field of operation. If the surgeon wished to operate while standing the chair part of the mechanism could be raised. If, however, the surgeon desired to operate while sitting, the chair could be lowered

to the required level. If trouble arose in respiration the chair could be quickly converted into a table top in the Trendelenburg position.

Malignant Disease of the Upper Air Passages, with Notes Upon Two Cases of Epithelioma.—Dr. J. Price-Brown of Toronto presented this report with reference to ten cases of malignant diseases occurring in the nose, nasopharynx, oropharynx, and larynx. Seven of them were sarcoma of the nose; one was sarcoma of the larynx; one, epithelioma of the larynx; and one, epithelioma of the inner ala of the nose. These cases had all been treated by internal methods, chiefly by the oft repeated use of the electrocautery, in which on each occasion the parts being anesthetized by the free use of cocaine and adrenalin, as much of the malignant growth was destroyed as possible. In these cases, after cure seemed to be obtained, the patients were all kept under observation for a prolonged period of time; and whenever there was recurrence of the malignant growth it was at once attacked again in like manner, the new vegetations being destroyed. The results were eminently satisfactory, only one of the seven cases of sarcoma of the nose ending fatally. In the case of sarcoma of the larynx the fight between the growth and the cautery was still going on, after a fifteen months' siege; the aid of radium being added latterly. The prognosis was doubtful. In the case of epithelioma of the pharynx, six months after the first operation the man was still living although the end was hopeless. In the case of epithelioma of the inner side of the ala of the nose, the author was hopeful of an excellent result from the combined use of the electrocautery and radium; although the case was too recent to arrive at any positive conclusion at this time.

Report of a Case of Bronchoscopy for Multiple Foreign Bodies (Almond Shell and Pulp) in a Child Two Years of Age.—Dr. John R. Winslow of Baltimore cited the following case: Iona B., aet. 2, was playing upon the floor when her mother's attention was attracted by her crying, and she noticed that the child was blue in the face and breathing badly. She immediately held the child up by the feet, slapped her back, and running her finger down the throat removed a large amount of almond shell and pulp; this resulted in greatly improved respiration and the mother supposed that the nut had all been removed Since this time, however, the child had at times exhibited embarrassed respiration and occasionally cyanosis. Examination showed the respiratory movements much shallower on the left side and the respiratory sounds lost below the second rib; no râles present. Temperature 98°, pulse 118, respirations 28. The patient was admitted to the University Hospital and examined with Jackson's direct speculum under cocaine; by this means it was demonstrated that nothing was present in the larynx, and that the smallest bronchoscope then available (7mm.) would not pass through the subglottic space. Tracheotomy, followed immediately by lower bronchoscopy with a 7 mm. Jackson tube, was carried out on the following day. In this way a considerable amount of milky pulp was removed from the left lower lobe bronchus; the upper lobe bronchus could not be entered. No shell was found. Owing to the patient's bad condition further examination had to be discontinued after about thirty minutes. From the following day the patient developed a broncho-pneumonia lasting eight days. On the thirteenth day the patient was discharged from the hospital in an enfeebled but otherwise normal condition, and returned to her home and the care of her physician, Dr. F. G. Wright She remained in good condition for about a month, and then, in consequence of an epidemic influenza, again developed pneumonia. Following this the wound opened spontaneously and she coughed up an oval piece of almond kernel about 6 x 3 mm. She then slowly but fully recovered. The essayist called attention to the difficulties of bronchoscopy in very young children, owing to the small size of the respiratory passages, the difficulties of instrumental manipulation, and the nature of the objects usually encountered. He discussed the best methods of procedure in such cases. While admitting the obvious advantages of upper bronchoscopy (without tracheotomy) he noted its disadvantages. A study of cases reported showed that while upper bronchoscopy had been attempted many times for the removal of foreign bodies in infants, in a large percentage, if not the majority of them, tracheotomy had become ultimately necessary for successful removal. Reference was made to a recent article by G. Killian in which he called attention to the frequency with which tracheotomy or intubation became necessary after upper bronchoscopy, even when successful. This he attributed to an edema of the subglottic space caused by traumatism. In some of the cases recorded he showed that the bronchoscopic tube used was too large for the subglottic space. Under these circumstances, while admitting that the selection of method must be individual in every case, the author concluded that in the majority of cases in young children, lower bronchoscopy was preferable to upper, in that it was easier, surer, and safer. In support of this view he cited numerous authorities

Traumatic Paralysis of the Right Recurrent Laryngeal Nerve.—Dr. Bryson Delavan of New York City reported two cases, the following being the history of one of them: Elizabeth X, aged 23; otherwise healthy with no relevant history; speaks in a hoarse tone of voice of peculiar quality; this is worse in bad weather, when she is fatigued or when she has a cold. States that when 12 years old and fairly well grown she tripped in crossing a railway track and fell, striking her throat upon the inner edge of the opposite rail. The fall was hard and the shock severe. Upon striking the rail she uttered a loud cry, but upon attempting to speak immediately thereafter found that she had lost her voice. She was treated at various times and places, but principally at the Massachusetts General Hospital. Applications were made to her throat and the use of electricity was employed for a considerable length of time. No good results followed any attempts at relieving her. Eleven years after the accident she was examined by the writer. She appeared normally developed, well nourished and healthy. She occupied the position of waitress in a summer hotel, and filled her place satisfactorily in every respect. Laryngoscopic examination showed the right side of the larynx fixed, with the vocal band drawn a little to one side of the median line. The anteroposterior length of the right vocal band was distinctly shortened to the extent of one-third. Fixation was absolute. The cord was slightly hyperemic and the whole of that side of the larynx appeared contracted. The left side of the larynx was in every respect normal, both as to appearance and physiological function. It appeared evident that at the time of the injury to the larynx the right recurrent laryngeal nerve had been completely paralyzed. The prognosis in this case as to recovery was absolutely bad. There was no reason, however, why the patient should not enter upon any of the ordinary avocations of life with success; the great point being to avoid all sources of irritation to the larynx, and in case of the occurrence of a laryngitis of the simplest type, to resort to proper measures for its relief at the earliest possible moment, as there had been occasions during the existence of catarrhal states of the throat when slight dyspnea had been present. The patient was advised of the importance of avoiding laryngitis, and it was suggested to her that she report back to the Massachusetts General Hospital for periodical examinations of her throat at intervals of not more than a year in order that the history of the case might be kept in mind and that she herself might be under the supervision of some competent specialist. With a little care in the above particulars there was no apparent reason why this patient should not live out the full term of a useful existence.

The Question of Postoperative Nasal Packing in the Light of Additional Experience with the Author's Rubber Tampon.—Dr. W. E. Casselberry of Chicago called attention to the fact that a posterior pack of some sort must at times be inserted in order to control a dangerous degree of post-operative hemorrhage, especially that liable to ensue some hours after the severing of a principal branch of the postnasal artery, as in turbinectomy and the sphenoethmoid operation. As these were the operations and this the pathway, for the intranasal surgical drainage of the sphenopostethmoid group of accessory sinuses, the severing in trunk or branch of this particular artery now so often confronted us that a satisfactory safeguard against subsequent hemorrhage had a very practical bearing on the extent to which this much needed surgical treatment was likely to be utilized. The fact that plugging the posterior naris would succeed in stopping such a hemorrhage even though a well placed anterior pack had failed, was due to the ring-like conformation of the choana against the bony edge of which the trunk of the postnasal artery, as it emerged from the sphenopalatine foramen, together with its principal branches, was necessarily compressed by any plug which got snugly into the choana or was held against it by forward traction. A preventive tampon therefore, competent to prevent hemorrhage at this site, must possess a postnasal feature, an advantage imparted to the new combination nasal and postnasal aseptic rubber tampon shown in 1909, by a bulbous expansion of its distal end which had not once failed to fulfill its purpose, having been utilized by the author as a primary dressing at

the close of all operations reputed to be liable to secondary hemorrhage, numbering some 175 private cases, and having enabled him, without fear of hemorrhage, to extend the benefit of nasal surgery to many more persons in need of it than would have accepted an exclusively hospital procedure. He stated that the antipathy to nasal packing in general and the advice of authors against postoperative nasal packing in particular, were based upon the old-time necessarily septic tampon of uncovered gauze which, it was agreed, should be quite abandoned; but he insisted that these negative views were inapplicable to the non-absorbent smooth surfaced aseptic rubber tampon, for in not a single instance of his series which embraced many cases of sphenoethmoid and other sinus suppurations, did it induce or contribute to infection of the ear, meninges, sinuses, or any septic condition; and if its general use as a preventive of hemorrhage were not restricted by prejudice it would be instrumental in multiplying the beneficiaries of nasal surgery. In all cases the tampon has been withdrawn in from 15 to 18 hours and in not over 5 per cent. had it been necessary to reinsert it for another period of equal brevity. In order to obviate the only uncertain element the author had recently added an anchoring cord, within the rubber, to the postnasal bulb, by which any shifting of it away from the vessels to be compressed in the choana might be prevented. A single strong black silk thread was tied to the first few inches of gauze, enfolded into a small knot, just as it emerged from the distal end of the packer, before the rubber was slipped over it. The string therefore during the insertion of the tampon led forward along the outside of the packer, but inside of the rubber case, being held taut till completion of the gauze packing by the same hand that held the packer, when by gently pulling the string and affixing it to the front end of the pack by a few turns around a fold of gauze or cotton, the postnasal bulb was drawn snugly into the choana and held against its ring-like bony edge in the same manner and with equal efficiency as an ordinary postnasal plug, but with the advantage that both gauze and string were incased in rubber.

The Anatomy of Deflections of the Nasal Septum.—Dr. Otto T. Freer of Chicago gave an account of the anatomy of the deflected septum as revealed to him by his submucous resections by the open method. It was his opinion that the anatomical conditions alone showed the way to correct deflections and that these conditions proved that crude preconceptions as to their nature led to some of the imperfect and harmful operative methods now in use. He divided deflections in the customary way into traumatic ones and those from growth. The latter were by far the commonest and their chief form was the crista lateralis or ascending crest deflection, or horizontal angle of deflection, as he called it, which followed the anterior border of the vomer upward and backward, creating the well-known crest or ledge so often sawed away. These deflections were due to vertical growth pressure upon the septum, which grew too fast for its frame, and so had to bend out of the median plane. While the pressure created a bending out of the vomer, perpendicular plate, and cartilage to form a horizontal angle of deflection, it also caused the cartilage to override the vomer, not in the form of a dislocation of the cartilage from its vomeral groove, as had been supposed, but by the cartilage, in its downward travel, carrying its entire articulation with the vomer with it so that the bony face of the articulation instead of looking upward, as it normally did, was found upon the side of the vomer slanting into the naris of the convexity. The ledge or crest found in these deflections in the naris of the convexity was that flange of the vomeral groove which in this displacement came lowermost and which coincided with the downward displaced posterior inferior border of the septal cartilage, hypertrophied into the usual cartilaginous crest. Back of the cartilage the vomer and perpendicular plate joined to form a bony V or angle, which permitted the cartilaginous strip in its articulation to escape upon the convex side of the angle, forming there a continuation of the cartilaginous crest backward. In less frequent, but still common, cases, the vomerocartilaginous articulation instead of tilting into the naris of the convexity, slanted into that of the concavity, so that the cartilage, in order to follow it, bent horizontally upon itself. In these cases the operator encountered rising from the nasal floor a high, bony, vomeral wall right under the mucosa periosteum in the naris of the convexity, and on the other side of the wall found the cartilage descending into the naris of the concavity while in the common type of crest deflection he came first upon cartilage. The deflections of the anterior inferior free portion of the septal cartilage and their influence in producing a slit-shaped nostril were also described. Rounded vertical angles in the cartilage were attributed to horizontal growth pressure between the sphenoid body and nasal bones. The combination of such a vertical angle with a crest deflection make a double-angled deflection. A horizontally sigmoid deflection resulted when the concavities of these two deflections alternated. Surgically important was the crossing of the periosteum and perichondrium in the crest deflection across the septum from naris to naris in the vomerocartilaginous articulation. Traumatic deflections were usually purely cartilaginous and in their commonest form created a vertical, sharp-angled deflection far forward in the naris, often in the nasal vestibule. The fragments of the old fracture were usually found ununited, so that each was contained in its own perichondrial envelope and a fibrous bridge joined the mucous coverings of both nares through the fissure between the fragments. In numerous instances the fragments overlapped, and in these cases the angle of deflection was replaced by a greater thickening of the septum, especially in growing persons, where the fragments continued to grow past each other. Because of these complicated fibrous envelopes, which interrupted the denudation of the cartilage in the submucous resection, perforations in traumatic deflections was common unless keen dissection supplanted the attempt to detach the coverings with a blunt elevator.

The Middle Turbinated Body: Some Indications for Its Removal.—Dr. W. Scott Renner of Buffalo stated that enlargement of the middle turbinated bone might be responsible for a definite train of symptoms where no other systemic cause for their development could be ascertained. In 300 such cases treated during the past six years, frontal headache and eyestrain occurred most frequently: paroxysmal sneezing next; and third in order, cases of acute frontal sinus and ethmoid trouble. Other symptoms were: reflex cough: at times asthma; vertigo; and twitching and spasm of the ocular muscles. The removal of the middle turbinated bone was indicated for the relief of these symptoms and for the proper ventilation and drainage of the nasal accessory sinuses. Attention was invited to the fact that this did not refer to cases of chronic sinusitis and nasal polypi in which the enlarged turbinate required removal as a part of more radical operations. Deflections of the upper portion of the nasal septum might require correction before or after the removal of the middle turbinated body.

Vincent's Angina: Its Frequency and the Importance of Its Diagnosis. With Reports of Two Fatal Cases.—Dr. Thomas H. Halsted of Syracuse stated that Vincent's angina was the manifestation in the throat and upper respiratory tract of the infective activity of the fusiform bacillus associated with spirochetes and spirilla, these latter being probably but evolutionary forms of the former. These same organisms produced disease in all parts of the body, a pseudomembrane being produced on mucous membranes, and abscesses in the deeper parts. Hospital gangrene and noma were due to these organisms, while many cases of phagedenic ulcer of the penis and genitalia and abscesses of the lung and spleen had been reported, and recently a case of appendicitis followed by general pyemia with multiple abscesses in all parts of the body, due to the fusiform bacillus, had been reported by Tunicliffe. Many cases of bronchitis, laryngitis, bronchopneumonia, the false membrane being the local lesion; a few cases of mastoiditis, the fusiform bacillus being the pathogenic organism in all of them, were found in the recent literature. Vincent's angina, strictly speaking, was the disease as seen in the mouth, fauces, pharynx, and larynx. There were two distinct clinical types—one resembling diphtheria so closely that the best observers were likely to err in diagnosis, while the other type simulated so nearly the throat lesions of syphilis, the mucous patch, the tertiary ulcer, and even the initial sore, that unless one were careful he would be likely to mistake an ulcer of Vincent's angina for a syphilitic ulcer. A positive diagnosis was easily made by bacteriological examination of a smear taken from a gentle curettage, or a swab, preferably the former, of the under surface of the pseudomembrane, or of the ulcerated surface itself. It might not be found if the smear was from the outer surface of the pseudomembrane. The organisms, which were anaërobic, did not grow on the ordinary culture media, and hence were always overlooked by the bacteriologist in examining cultures for diphtheria, which accounted for the supposed infrequency of the disease. The disease was altogether more frequent than had been suspected. Statistics were given to prove this statement. It was probable that 20 to 25 per cent. of cases, diagnosed clinically as diphtheria and reported by the bacteriologist

as being simply negative, were Vincent's angina, but were not discovered by the bacteriologist as he examined only the culture and not the smear. The writer found that of the last 2500 cases of ear, nose, and throat disease seen in his private practice, 20, or 1 in 125 were Vincent's angina The writer reported two fatal cases. In one case the disease occurred in a woman eight months pregnant. The membrane, resembling that of diphtheria, was most profuse and was present not only in the mouth and throat, but also in the vagina. It persisted for two months in the mouth and throat despite treatment. A very foul, fetid odor, peculiar saffron color to the skin, great pain in swallowing interfering with nourishment and sleep, low temperature and profound toxemia with great prostration were the prominent symptoms. The patient died suddenly at the onset of labor. The second case occurred in a young woman, the pseudomembrane covering the aveolar borders and the buccal mucous membranes, causing such great pain that she could not swallow, refused all food and practically starved. A most profound toxemia and secondary anemia developed, the patient finally succumbing to the disease. The writer derived most satisfaction in the treatment of the mild cases by the use of trichloracetic acid to the ulcerating surface, orthoform relieving the pain, while in many improvement followed only after the diseased teeth and gums were cared for. Tincture of iodine was useful in many cases. General tonic treatment was always necessary. In the severe cases resembling diphtheria clinically, local treatment was unsatisfactory. No specific treatment had yet been evolved, but it was hoped that an antitoxin or vaccine might be developed, or possibly that salvarsan might prove effective against this spirochete as well as against that of syphilis.

Complications of Tonsillectomy.—Dr. Charles W. Richardson of Washington, D. C., referred in this paper to the fact that the complications of tonsillectomy had not been reported as they should have been, and this accounted, no doubt, for the small number of cases reported in the literature at the present time. He divided the complications into their various classifications. Hemorrhage predominated in the frequency of reported complications. Fifty cases of serious hemorrhage were reported, with nineteen deaths. Two interesting cases of hyperpyrexia were recited—one in the practice of Dr. Wishart and the other in Dr. Richardson's practice. Infarct of the lung was reported, but, because the cases were reported verbally and did not appear in the literature, no use of them was made. General sepsis of a mild type was of frequent occurrence; it was not infrequent in severe form. Several interesting cases of profound sepsis were narrated. The other subjects treated of in the paper were emphysema, infection of the lungs and serous membranes, disturbances in relation to the nervous system, and status lymphaticus. Under the last named Dr. Richardson reported two interesting cases by Drs. Packard and Harris. Under other sections were treated amygdalotomy, rash, diphtheria, and local disturbances as sequelæ of tonsillar operations. Other interesting accounts were given of injuries and reference was made to the rather severe arraignment by Dr. G. Hudson Makuen of injury to the pillars and to the soft palate. Small space was given to the consideration of infection of the ears and cervical glands. In the unclassified list were grouped a number of complications referring particularly to Crockett's statement of twelve deaths having occurred in the suburbs of Boston in the last year and a half. The conclusions of the paper were as follows: "If anything can be gleaned from the reports which I have enumerated above it would seem to be that tonsillectomy may be at times attended by most serious, even fatal, complications. It behooves us, therefore, to be most careful in our technique and most cautious in our postoperative attention to our patients. Tonsillectomy, therefore, should be considered a major operation and the patient should be prepared and surrounded with all the post-operative attention as in any major operation. With such knowledge, is it proper and wise to suggest this operation, as is so often done by the internist, with insufficient and inaccurate data from a local standpoint, as a prophylactic measure? I believe that this point of view, as an overwhelming demand for the removal of the tonsils, is too often presented to the reluctant patient. I believe that a few general conditions probably have their portal of entry into the general system through the tonsils, but I would demand that, in every individual case, the tonsil be first proved to be guilty before it is sacrificed. One must hold steadfastly in mind the fact when suggesting such a procedure under such conditions that we by this operation are placing the patient in danger of his life—probably a greater danger to his life than the probable remote infection."

Dr. Wishart of Toronto said that he had heard of no other case excepting that now reported by the author at all like the one reported by him and referred to in this paper. He believed that hemorrhage was not abundant in cases of tonsillectomy unless there was a tearing of considerable muscle around the tonsil; that when one stuck closely to the capsule he got very little hemorrhage. He thoroughly endorsed the view that tonsillectomy was a major and not a minor operation and said that the time had come when this should be definitely established.

Dr. Beck of Chicago called attention to the operation he was using at present and which was followed by absolutely no hemorrhage. It was the method employed by Dr. Sluder of lifting out the tonsil and then snaring it off slowly; with this neither traumatism nor hemorrhage follow, for there was no possibility of including the pillars, the uvula, or anything except the tonsil itself. He mentioned a case of abscess of the lung which was considered to be due to enucleation of the tonsil. The speaker then referred to a case of amygdalar scarlatiform rash admitted to the Cook County Hospital for scarlet fever; the patient became infected with diphtheria and required tracheotomy, and it was later discovered that it had not been scarlet fever at all, but that the rash was that sometimes seen following tonsillectomy. He considered that the general practitioner should be made familiar with this condition, and possibly thereby obviate the possibility of his patients becoming infected with a contagious disease in the isolation hospitals.

Dr. Bryan of Washington, D. C., spoke very strongly on the subject of this paper, stating that it was his opinion that the public should be educated to regard the operation of tonsillectomy not as a trivial matter but as one of equal seriousness with other major operations, and he considered this but rational, in view of the many complications following its performance, many of which were most serious. Furthermore he contended that only a qualified and properly equipped operator should perform this operation and that it should by no means be entrusted to the hands of a tyro.

Dr. Freer of Chicago gave as his opinion that the tearing out of the tonsil by blunt instruments or blunt force was responsible for much of the hemorrhage and sepsis following tonsillectomy, and that he most heartily indorsed the use of a sharp knife for excision of the tonsil, believing that this glandular tissue should be treated in the same way that a surgeon would treat a bubo of the groin. Following the performance of the operation by this method he had had absolute satisfaction in hundreds of cases, without alarming hemorrhage, sepsis or undue reaction.

Dr. Delavan of New York City called attention to the acknowledgment on the part of a pediatrist in his city that he had operated in 800 cases for removal of the tonsil and that he always excised a swollen tonsil in a child. Dr. Delavan condemned this practice absolutely, first with regard to the person operating because he was not a regularly experienced throat man and therefore not properly equipped for all emergencies, and second with regard to the attitude of always removing a swollen tonsil in a child, which showed that the practitioner in question was not familiar with the function of this organ nor aware of the seriousness at times of removing it, especially when the throat was in a septic condition.

Dr. Casselberry of Chicago agreed with the last speaker in that few general practitioners or pediatrists were properly equipped with means of controlling hemorrhage to be considered qualified to perform the operation of tonsillectomy. He acknowledged that in most exceptional cases, such as the case of a hemophilic child or when the ascending pharyngeal artery was severed, due to an anomalous position of this vessel, it might be impossible even with the best equipment to stop the hemorrhage except by the use of a hemostat. He considered that it was the laryngologist's duty to protect himself against the accidents following tonsillectomy by being always on the lookout for the all too frequent emergencies, and having always at hand instruments and means for the control of unexpected accidents.

Dr. Ballenger of Chicago considered that the paper by Dr. Richardson presented the condition of affairs in a most alarming way, referable to the technique of former days rather than to the improved and careful technique used at the present time. He did not agree with Dr. Sluder, although commending his method, that severe hemorrhage did not follow it just as surely as it followed other methods. He considered the safest removal of the tonsil was first by partial dissection, and then the use of the snare, although even this method had been followed by hemorrhage. He mentioned a case in which following a tonsillectomy he had the misfortune to have a general septicemia develop which laid the patient up for six

months, although he finally recovered. He could not explain why hemorrhage did occur in the use of the Sluder method, except at the time he used this method he used ether anesthesia, and he had concluded that the hemorrhages which resulted were due to the high blood pressure caused by the anesthetic rather than to the technique of the operation. He indorsed what previous discussors had said in regard to the importance of warning the inexperienced and illy equipped man from undertaking the operation of tonsillectomy.

Dr. Roe or Rochester, N. Y., called attention to the mutilation of the throat resulting from tonsillectomy, and said that he had seen two cases of complete adhesion of the soft palate to the pharynx, the soft palate having been removed instead of the tonsil. He cited one fatal case of a hemophilic patient from whom he removed the tonsils; there was no immediate hemorrhage, but later a continuous oozing took place, which nothing could stop.

Dr. Price-Brown of Toronto sounded a warning against operations on the tonsils in patients suffering from chronic rheumatism, and reported an illustrative case in which following tonsillectomy the patient began to bleed and it required heroic measures to control the hemorrhage, and it was several weeks before the patient rallied from the shock. He considered that the arterial sclerosis existing was the cause of this hemorrhage.

Dr. Winslow of Baltimore related his method of procedure to ward against hemorrhage in cases of tonsillectomy, saying that this was the method adopted throughout the hospital with which he was connected, namely, the ligation of every bleeding vessel and every bleeding piece of muscle at the primary operation, by this means making it possible always to return the patient to bed perfectly dry and with no greater fear of subsequent hemorrhage following a tonsillectomy than following any major abdominal operation. It was his opinion that sepsis seldom occurred unless there had been unnecessary injury to the tissues, and for this reason he advocated the employment of a method requiring the least possible amount of injury to tissues. He stated that he was frequently bothered with a peculiar condition after a tonsillectomy, the patient complaining of a sensation of dryness in the throat for which the operator could not account and which he could not relieve, although this sometimes disappeared in time, while in other cases it persisted.

Dr. Sluder of St. Louis in regard to the method of technique called by his name, called attention to the fact that he had recommended the use of a dull blade and guillotine for this purpose, whereas he was sorry to say that the instrument maker persisted in providing a sharp blade in the instrument on the market sold as pretending to be that recommended by him. He himself did not use that instrument, but a modification of it. He stated that in 300 cases of children varying from 2½ to 15 years he had measured the amount of blood lost by his technique, and the average loss of blood was 70 c.c. after removal of both tonsils and adenoids. At the St. Louis Children's Hospital, where they had about ten children every Friday for tonsil operations, it was routine practice that a blood test be made beforehand to ascertain the time of clotting; the puncture was made at the same point in the lobe of the ear and by the same instrument, and the same means of computing the clot were used, and by these means not only was there made an estimation of the amount of blood which would exude from a like point from the same instrument, but also there was an estimation of the resilience of the vessels of the particular individual. He never accepted a child for operation with a clotting time beyond a minute and a half. He referred to such a case upon which he refused to operate: the child was taken to another laryngologist who promptly removed the tonsils, and the patient almost bled to death. No child was accepted for operation with a temperature of more than 99.2°.

Dr. Wagner of San Francisco reported a case operated on some two years after an attack of diphtheria for the removal of the tonsils. A bacteriological examination was carefully made of the secretions of the throat which were found negative; no examination, however, was made of the secretions of the nose, and following the tonsillectomy the patient developed a diphtheritic sore throat, the infection springing from a little necrosed spot on the middle turbinate which still harbored the diphtheria bacilli. He endorsed Dr. Winslow's method of ligating the vessels and bleeding muscular tissue during tonsillectomy, and said that this was also his practice. He did not believe that the results obtained from estimation of the coagulation time of the blood were always reliable, citing in this connection the case of a boy of 10 in whom the estimated time was satisfactory and yet who bled terrifically after operation, the hemorrhage finally being controlled by the use of diphtheria antitoxin.

Dr. Chenery of Boston recalled a case of a man of 35 operated on in a hospital, who being an alcoholic was kept under observation for some days before being allowed to return home; twelve hours after his return home he began to bleed, a general practitioner was sent for to stop the bleeding, but he simply took a wad of cotton and wiped it round the back of the throat, thus increasing the bleeding; the operator could not be reached and therefore the speaker was called in after several hours and was able after much difficulty to stop the hemorrhage by the application of nitrate of silver to the tonsil. He considered that it was very important to carefully watch patients addicted to the use of alcohol after such operations. He had found the use of rabbit's serum very efficient in the control of hemorrhage.

Dr. Harmon Smith of New York thought that if one considered the vast number of tonsillectomies performed the mortality would be shown to be extremely small; in fact, smaller than that following any other operation performed under ether anesthesia. He said that in the laboratory of the Manhattan Eye, Ear, Nose and Throat Hospital they made a preparation of thrombokinase which was very useful for the stoppage of oozing, although not efficient for overcoming violent hemorrhage. This thrombokinase would be furnished to practitioners upon request.

Dr. Pierce of Chicago related the case of a man who had his tonsils removed without any previous preparation. The patient was a full-blooded man, and during the day had indulged more or less in liquor. In the evening his physician removed the tonsils and the patient bled to death that night. He cited this instance as an example of the serious results from the taking of no precautions, but considered that the operation of tonsillectomy when proper precautions were taken, was practically devoid of danger, in the hands of men skilled and well equipped.

Dr. B. R. Shurly of Detroit recited a case in which previous to operation, in order to make sure of no subsequent hemorrhage, he administered calcium lactate to the patient. The operation was performed by the use of the knife, and the most terrible hemorrhage in his experience resulted.

PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Forty-eighth Regular Meeting, Held May 3, 1912.

The President, Dr. Brannan, in the Chair.

Syphilis of the Liver.—Dr. Roper showed a patient who had been admitted to New York Hospital on August 5, 1912, with a history of gonorrhea and chancroid infection twenty years before. He had used alcohol to excess up to four years before admission, but none during the last four years. Aside from hemorrhoids, which had been troublesome for two years, he had been well until four weeks before admission, when he noticed that he was slightly jaundiced. On several occasions about this time he felt dizzy on getting up in the morning. One week before admission he had noticed that his abdomen was swollen. Constipation and some abdominal pain had also been present during past month. On admission patient showed an emaciated body, a distended abdomen, and swollen legs. Liver extended from the fifth intercostal space to 3 cm. below costal margin in mammary line; edge was palpable. Spleen was very large, being within 2.6 cm. of umbilicus and extending below to anterior superior spine of iliac bone. He was unable to lie down because of dyspnea. Two weeks after admission a positive Wassermann was obtained. Up to this time improvement had not been satisfactory. Five days later 0.5 gm. salvarsan was given intravenously. After this the patient rested better. There was no effect on ascites, however, so 6,500 c.c. of clear fluid were withdrawn. There was no reaccumulation of fluid and the patient's general condition improved very rapidly. Since discharge he had attended to his usual occupation of truck driving and his health had been very satisfactory for a time. Two Wassermann reactions taken within a few weeks of the salvarsan treatment were anticomplementary. Three days ago patient gave a positive Wassermann, and, while there had been no return of fluid or edema, dyspnea on exertion returned. In the right lobe of the liver a large mass could readily be palpated. This was probably a gumma. Dr. Roper also showed a liver from a similar but more advanced case that had been under observation at New York Hospital for four months before death.

Patient was a German waiter twenty-eight years of age, who had had gonorrhea eight years before, but denied knowledge of luetic infection. He had used alcohol freely as wine, beer, and whiskey. He had been well up to one year before admission, since when loss of weight and weakness had interfered with his work. Jaundice had developed four weeks before admission. Physical examination showed a liver extending from fourth space to 13 cm. below costal margin in nipple line. Left epididymis was hard, swollen, and there were scars over both shins. Tibiæ were roughened. Patient gave a positive Wassermann reaction on September 8, 1912. On September 12 he was given 0.5 gm. salvarsan intravenously. His temperature, which had been rising to 103° daily, remained normal for two weeks after injection. Then it again began to make daily excursions to 103°. After four days of elevated temperature, 0.6 gm. of salvarsan was injected intravenously and the temperature again returned to normal. The Wassermann reaction was strongly positive on September 18 and 30. Potassium iodide had been given up to 150 grains a day. Mercury by hypodermic injection caused prompt salivation and an obstinate stomatitis. The patient's general condition improved so that he was able to go home although still showing edema of extremities and jaundice. Seven weeks later, December 20, 1911, he was readmitted in much the same condition as on first admission. His Wassermann reaction was positive and he was running a slight elevation of temperature. After 0.6 gm. salvarsan, temperature remained normal. Six days later another 0.6 gm. of salvarsan was given. An attempt to renew mercury medication resulted in an aggravation of his stomatitis, which had persisted. Probably from this source on Jan. 14 the patient developed septicemia, *Streptococcus longus* being isolated from the blood. He died four days later. Autopsy showed smooth atrophy of tongue, a deformed epiglottis, a spleen weighing 4 pounds, showing evidence of diffuse syphilis, a left testicle showing interstitial orchitis. The liver weighed 5 pounds and was greatly deformed, numerous depressed scars subdividing the lobes. Just below the attachment of the subdividing ligament the liver was studded with small gummata from 2 to 4 mm. in diameter, embedded in dense scar tissue. A similar condition was present at right anterior margin. Balance of organ showed appearance similar to that encountered in alcoholic cirrhosis. Tissues of liver, kidneys, and spleen were tested for arsenic and mercury. No arsenic was demonstrated (control tests were positive). A trace of mercury was found in kidneys, but none in liver or spleen. The interesting features of the case were the apparent effect of salvarsan on the temperature, the failure to influence the gummata by treatment, and the intolerance for mercury.

Dr. Meara asked if fever due primarily to syphilis was not uncommon in the tertiary stage. It had been his impression that unless due to a secondary infection fever was not a feature of tertiary syphilis.

Dr. Starr thought that in the tertiary stage an elevation of temperature was very rare. A temperature of 101.5° or 101° was not uncommon.

Dr. Gibson said that in regard to reducing the size of the liver it had been a common experience to see this happen very readily under the old form of treatment. He had seen great big livers go down within the space of two or three weeks. Of course, some responded more promptly and satisfactorily than others.

Dr. Roper said that fever did occur in syphilis of the liver, some of the cases of gumma of the liver having been mistaken for abscess because of the swelling, tenderness, and fever. The temperature in the case reported had fallen so promptly on two occasions after giving the salvarsan that it seemed to exclude any coincidence.

Accessory Pancreas in the Gastrointestinal Tract.—Dr. C. L. Gibson read this paper. (See page 426.)

Absence of Döhle Leucocytic inclusion in a Case of Suspected Scarlet Fever.—Dr. Park said that about three months ago Döhle had called attention to the presence of small bodies in the polymorphonuclear leucocytes in cases of scarlatina. These bodies were present in every leucocyte in many cases, but in other cases only one leucocyte in three or four would contain them. They were always present during the first four days of the disease. After this they lessened in number, but were sometimes found up to the fifteenth or sixteenth day. They had also been found in one case each of pneumonia, carcinoma, and syphilis, but absent in other cases examined. The work of corroborating these findings has been taken up by Drs. Williams and Nicoll at the Health Department Laboratories. Dr. Park cited a case admitted to Willard Park Hospital as scarlatina with a typical rash but a non-characteristic throat. No bodies were found in the blood of this case. No desquamation ensued and the patient was discharged as "no case." Repeated examples of positive results had been had. He said that in undoubted cases of scarlet fever it was their opinion that the bodies would always be found in well developed cases of scarlet fever. They were not so abundant in the lighter cases. Conditions simulating scarlatina, such as German measles and antitoxin rashes, were uniformly negative. The bodies were present, however, in cases of sepsis. Dr. Park also cited a case of scarlet fever in which, after almost complete disappearance of the bodies, they returned in abundance on the development of a septic complication. The department was now prepared to make this examination regularly for outside physicians. Smears should be made as for malaria examinations.

Dr. Meara asked what technique was used in staining the bodies.

Dr. Park answered that borax methylene blue was the stain regularly used, but any of the aniline dyes would do; with the Giemsa stain the bodies are light blue and the nuclei of a reddish hue; with the Pappenheim stain the bodies are reddish while the nuclei are blue. The main point is to have a stain that will not make the granules prominent.

Dr. Conner asked if the bodies were present in the lymphocytes.

Dr. Park said that they occurred only in the polynuclears.

Dr. Dana asked what the composition of the bodies was and from where they were derived.

Dr. Park thought the bodies might be inclusions of portions of broken down cells or the protoplasm might be degenerated and coagulated; they occurred usualy in the periphery. They certainly were not parasites.

Dr. Dana remarked that the bodies probably consisted of proteid matter.

Dr. Park added that about 100 cases had been examined and in every case that pointed to scarlet fever the bodies were found, and always in the earliest stage of the disease. They occurred in one case in five or six of pneumonia.

General Septicemia Originating in a "Streptococcus Throat."—Dr. Gibson reported the case of a woman thirty-five years of age who had entered the hospital and died in less than forty-eight hours. She had been taken ill with sore throat one week before; it was stated that she had had one chill and possibly some fever. She had later developed some abdominal tenderness and had vomited. When she came to the hospital she looked extremely ill. There was moderate abdominal distention, some tenderness, but no rigidity. Her entire throat was bright red. She was apathetic when admitted, and later became irrational, delirious, with involuntary evacuations. Her temperature on admission was 101° and pulse 120. The temperature rose to 107° before death, and the pulse increased in rate proportionately. Leucocytes on admission were 19,000, 94 per cent. polynuclear. A second count showed 19,500 with 95 per cent. polynuclear. The admission diagnosis was peritonitis. A blood culture was taken but no throat culture. The blood culture showed a very virulent streptococcus growth within twenty-four hours. The patient died. The autopsy showed a diffuse, plastic peritonitis, but no focus of infection could be found. A culture taken from the uterus was negative, while that from one of the Fallopian tubes showed streptococci. Dr. Gibson wondered if this might not be a case of malignant sore throat such as had occurred in the epidemic in Boston. In some of the Boston cases a diagnosis of peritonitis was made and an operation performed. All of them, he believed, died. Dr. Gibson thought that perhaps we were going to have a similar epidemic here. That was the reason he reported it. The Boston epidemic had been accredited to infection from a certain milk supply, but he believed that this had been exonerated.

Dr. Meara had been greatly interested to see the various manifestations which might accompany streptococcus sore throat. Last winter, for instance, there had been so much glandular involvement, particularly of the cervical glands, that the pediatricians had been inclined to classify these cases as "glandular fever." This winter there had been very little tonsilar involvement, but an intense inflammatory sore throat not like an angina but more like erysipelas of the mucous membrane. Some cases of sore throat were accompanied or followed by marked sinus involvement. Dr. Meara thought this might be due to reduction of resistance in special tissues. These cases certainly occurred in everybody's experience. He was under the impression that an epidemic like the one in Boston had occurred in Chicago also.

Dr. Park had been waiting for the epidemic to come to New York. Deerfoot farm had not been absolved, and he thought it was largely responsible for the Boston epi-

demic. Baltimore and other places in New England also had had epidemics. The Baltimore people suspected that it had a connection with the milk. At a time when one dealer stopped pasteurizing the cases increased. The cases from Chicago had had prolonged symptoms and a very severe inflammation of the throat. The organism isolated in the Baltimore epidemic was an encapsulated streptococcus.

Dr. CONNER wished to know, if one assumed that the infection occurred through milk, whether the point of entry was the tonsil or was the gastrointestinal tract. He thought that under those circumstances infection was unlikely to occur through the tonsil. If the intestinal tract was the portal of entry it might explain the frequency of peritonitis. If infection did occur through the intestinal tract it would suggest that the tonsillitis might be of hematogenous origin.

Dr. PARK said that there had been about 1,800 cases in Boston, and, while all had tonsillitis, only a few had had peritonitis. Infection through the tonsils was not difficult. In this connection the number of the organisms and their virulence was important. Dr. Park recalled a rabbit infected through the mucous membrane of the nose by a few organisms dropped into it from a very virulent streptococcus culture. Here death occurred from septicemia within twenty-four hours. Infection with bovine tuberculosis had occurred frequently by way of the tonsils, and other organisms, if virulent and present in numbers, might readily find entrance here.

Dr. GIBSON said a great many cases were operated upon for peritonitis, especially in the early part of the Boston epidemic.

Dr. BRANNAN said that Dr. Jacobi had always spoken of streptococcus sore throat as contagious or infectious, and wondered if that might not have been the same thing.

Dr. PRUDDEN said that the frequent insistence by Dr. Jacobi in the early days of bacteriology to which Dr. Brannan alluded, upon the differentiation of streptococcus sore throat, marked the period in which some forms of pseudo-membranous pharyngitis and laryngitis had just become clearly distinguished from diphtheritic inflammation by the absence of the diphtheria bacillus and the demonstration of streptococci. While this distinction was now generally recognized, it required a good deal of missionary work, both in and out of the laboratories, to delimit the time-honored, though somewhat hazy, conception of a condition then called croup, and to establish the conviction that the clearest essential in true diphtheria lay in the bacillus and its poisons.

Dr. CONNER said that one saw every winter in adults pseudo-membranous throats which were due to streptococcus. The constitutional disturbance was not the same as that of ordinary tonsillitis.

Hypernephroma Associated with Tuberculosis of the Kidney.—Dr. GIBSON presented a specimen from a male patient who had been a hospital inmate for some time because of chronic tuberculosis. He had improved for a time, but recently developed pain in the side, with frequent urination and pus and blood in the urine. On ureteral catheterization there was pus coming from one side. This specimen contained tubercle bacilli. The other side was negative. This kidney was removed and a section showed, microscopically, hypernephroma. The kidney also presented the appearance of tuberculosis. There seemed to be no question as to finding tubercle bacilli in the urine at the time. The patient had improved since the operation. A nodule in the skin of this patient had been reported microscopically as fibrosarcoma. A hypernephroma is a malignant tumor of the kidney developing from either the suprarenal capsule or from some aberrant portion of it.

Dr. DANA said that he had recently seen a hypernephroma in the brain cortex, producing local epileptiform convulsions. It was secondary to a kidney tumor.

Dr. MEARA asked how frequently hemorrhage had occurred in cases of hypernephromata not associated with tuberculosis.

Dr. GIBSON answered that it depended upon the extent and also upon the situation of the tumor.

Dr. PRUDDEN said they were occasionally found at autopsy, having given no symptoms at all.

Dr. GIBSON thought that they were quite chronic, the patient living several years without metastases. They attained a good size, all of twice the size of the original kidney. Middle life was the most common period for their occurrence; cases in children seemed to be more acute and ran a shorter course. He thought that all was not known about hypernephroma.

Dr. BIGGS reported an interesting case of hypernephroma which recently had been under his observation. The patient was a young woman who had very marked and severe digestive symptoms continuing over a long period and not relieved by simple measures. Examination of the abdomen showed a rather large, very movable, kidney on the left side. The right kidney, which was the one ordinarily movable, seemed to be of normal size and in normal position. After other means for relief of the symptoms had been unsuccessfully tried it was decided to fasten the kidney in position. At the operation a hypernephroma at the lower pole of the left kidney was found and it was this which had apparently dragged the kidney from its normal position. The size of the growth was about two-thirds of the size of the kidney. The organ and tumor were removed together. The patient did badly after the operation, had great abdominal distention and could not be relieved by any restriction or modification of diet and had also very rapid and feeble heart action. She developed a low grade of infection in the wound at the end of a week and finally died. At the autopsy, an old myocarditis was found with an extremely thin wall in the left ventricle. There was nothing in the history of the patient, who was only twenty-five years of age, to explain the existence of the myocardial disease. A curious feature of the case was the fact that the father and a younger brother both gave a history of disease of the myocardium and the father has since died from this cause.

Dr. GIBSON thought that a certain distortion of the pelvis gave a picture that was very suggestive of hypernephroma. He also thought that it was quite characteristic. The technique consisted of injecting the pelvis with some substance and getting an *x*-ray picture of the outline. He said that tuberculosis in combination with hypernephroma or other conditions was uncommon.

A Case of Tumor of the Spinal Cord.—Dr. STARR reported this case. The patient was a boy nineteen years of age. Two weeks before he had gone to him with a rather interesting history. He had suffered for two years from a considerable degree of pain and anesthesia under the right shoulder blade, along the neck, and on the under surface of right arm. This was increased on motion and by walking. Eight weeks before he began to notice that his right leg was weak and stiff. The next day his left foot and toes and leg were anesthetic up to the knee. The stiffness and rigidity of the right leg had advanced. He had weakness in the right leg and the anesthesia in both legs had extended up to the abdomen, somewhat higher on the left side. The rigidity and stiffness of the right leg increased; bladder and rectum were all right. There was no girdle sensation. The persistent pain under the right arm suggested localization of trouble to first dorsal segment. The probability was that the boy had a tumor of the spinal cord. The question of localization of the tumor was very interesting. The operation showed a small tumor at the first dorsal segment of the spinal cord. The fifth, sixth, and seventh cervical and first dorsal spines were taken off. Under the sixth cervical was found a small tumor. It was divided into two parts, one intradural was not attached to the cord but was pressing on the spinal cord; when they attempted to detach it it appeared that it was firmly attached to the dura and extended outside and downward pearshaped. It terminated in the nerve. It was necessary to divide the first dorsal nerve in order to remove the tumor. The boy had improved very much, had no pain and could move his legs and had almost normal sensation. He had anesthesia on the outside of his little finger from defect of nerve (eighth cervical). An operation must be done early in order to prevent secondary degeneration of cord from pressure. Dr. Starr thought the position of pain in the spine and periphery very important as a means of localization. He thought the tumor was probably a fibroma.

Dr. EWING thought that the thing most interesting was the diagnosis. The origin and nature were not available as no section had been made.

Dr. STARR said that the tumor was perfectly encapsulated, hard and most probably a fibroma. He said that it would be examined.

Dr. CONNER asked if there were no disturbances of skin sensibility in the area of pain.

Dr. DANA said that Dr. Starr's case illustrated the fact that the surgery of the spinal cord was very much more satisfactory in its results just now than surgery of the brain. He had recently seen two cases successfully operated upon at the New York Neurological Institute. Tumors of the cervical and cervicodorsal region were especially frequent in his experience. His experience had been that these tumors had been mostly sarcomata or fibromata. Surgery of the spinal cord had shown great advancement. Extramedullary tumors could frequently be very successfully operated on. Some intramedullary tumors have also been made available for operation by the Elsberg method, the operation being

done in two stages. One exposed the tumor in the first stage and in the other after ten days the tumor was easily removed. The cord itself seemed to squeeze the tumor out in the course of a few days.

Salvarsan in the Treatment of Chorea.—Dr. DANA reported a case of Sydenham's chorea of serious type which was promptly relieved by salvarsan. The patient was a young woman about eighteen years of age. She was brought to Bellevue Hospital with typical and violent clonic movements involving all the muscles. She was unable to walk or use her arms and her speech was unintelligible. She had no fever, her mind was clear, so that it was not a case of chorea insaniens, but only a serious choreic infection of the Sydenham type. She was given the ordinary treatment of isolation, arsenic, packs, etc., with some improvement. She was after a week still very violent and agitated, and could not control or feed herself. She was then given an injection of a half dose of salvarsan and at the end of twenty-four hours was very much better, she could feed herself, talk distinctly, and use her arms and went on to rapid convalescence. There had been no fever or endocarditis at any time, but this was not unusual in chorea. There was nothing in the blood, and he thought the Wassermann reaction was negative. Salvarsan was given because of the arsenic despite some reports that it was not arsenical in nature. Perhaps the overwhelming influence of arsenic would have the same effect. He had seen arsenical rashes after 606 and thought this drug must be arsenical in its action.

Dr. MEARA said that he had seen the patient and had been impressed by the apparently beneficial action of the salvarsan. The patient herself refused to go home when her friends came for her as she felt so much improved that she wanted to stay for further treatment.

Dr. CONNER spoke in regard to another case in which different therapy had been used with the same results. The patient, a girl in New York Hospital, had had the same symptoms as the case which Dr. Dana described She ran considerable temperature and her choreic movements were so violent as to interfere with sleep. Under arsenic, packs, etc., she improved and finally got up but still had twitching. Relapsed twice with same symptoms and very violent movements. The patient seemed of a type amenable to suggestion and hypnotism was tried with very striking benefit. The patient slept well, the choreic movements rapidly subsided and she made a complete recovery. It may have been a coincidence but it was very striking.

Dr. STARR asked if Dr. Dana had used sodium cacochulate by hyperdermic injection in chorea.

Dr. DANA stated that these cases generally got well under any plan of treatment but that he thought salvarsan had had an influence. He did not think that hypnotism would generally be of use in the early stages of chorea though certain results might be obtained with it. He thought that hypnotism should be used occasionally in chorea as well as in other conditions. He told of a case, a man about 35 years old, who was a dipsomaniac. The patient drank a great deal and would often have to lay off for weeks. Dr. Frink treated him by means of hypnotism. For two weeks he kept the man under hypnotic control and free from alcohol, which was better than any one had done previously. Now after a year of treatment the man said he could take one or two drinks and quit, when before he could not.

Antiseptic Power of Soap.—M. Pilod states that it is unnecessary to sterilize soap before use by means of heat, and that it suffices to wash off the surface of the cake of soap before use in order to dislodge mechanically the spores that may have accumulated there. For surgical antisepsis the bactericidal powers of soap cannot be relied upon, the scrubbing of the hands or operative field with soap for twenty minutes being insufficient for this purpose. All that this process can accomplish is the preparation of the skin, by saponifying the fats, for the action of more efficient antiseptics.—*La Presse Médicale.*

The Contents of the Vaccination Pustule.—J. Rosenfeld states that about the sixth day the vaccination papilla only rarely contains cellular elements; its contents are clear, pearly, and translucent. With the appearance and increase of leucocytes in the contents there occurs a coincident yellowing of the epidermis at the periphery of the papilla, whose color at this period is determined by the covering and not by the contents of the papilla. If the latter is secondarily infected its color departs from the normal and varies from a dirty gray to a pronounced yellow.—*Zeitschrift für Kinderheilkunde.*

Medicolegal Notes.

Presumption of Patients' Consent to Operation—Nurse's Opinion of Physician's Skill Inadmissible as Evidence.—Action was brought against a physician and surgeon for damages alleged to have been sustained by the negligent treatment of the plaintiff's foot The foot was injured by stepping upon a sewing needle, the point of which was supposed to have remained within the ball of the foot. An incision was made, but the needle point was not found. The foot became infected. Two other incisions were made in the effort to cure the blood poisoning. These were unsuccessful, and, after other physicians were called, it was found necessary to amputate the great toe. The chief contention in the case arose over the question of the unskillful use, or want of use, of proper antiseptics. One witness, a nurse, was permitted to testify that from a conversation she had previously had with the defendant, which she detailed, she did not think his standard of "technique" was equal to the standard of other physicians in the locality. Such a comparison was held to be objectionable and erroneously admitted as evidence, over the defendant's objection; but in view of the court's instructions to the jury and the testimony of physicians as to the defendant's reputation and standing as an educated and competent physician and surgeon, the error was held to be without prejudice.

The plaintiff asked and the court gave an instruction to the effect that the defendant had no right to make any other or different incision in the plaintiff's foot than he had obtained permission or the plaintiff had requested him to make. The defendant asked and the court gave an instruction that "consent to an operation will be presumed from voluntary submission to it, and the burden is on the plaintiff to prove the contrary." It was held that the two instructions, when taken together, correctly state the law.—Mosslander v. Armstrong, Nebraska Supreme Court, 134 N. W. 922.

Expert Evidence as to Automatic Muscular Action.—In an action by a workman for injuries caused by his fingers being caught between the die and the punch of a stamping machine he was operating, it was contended that the master was negligent in not warning the inexperienced plaintiff of the danger from the automatic action of his foot upon the treadle of the machine, as the result of a habit formed by the continuous and repeated operation of hands and foot in the same order. It was held that the evidence of physicians who had made a special study of the brain and nervous system, in answer to hypothetical questions, that, in their opinion, the continuous operation of the machine in the manner required would be likely to produce an involuntary sequence of muscular activities which would become automatic, and proceed without express brain action or will power, was fairly within the field of expert evidence, and admissible.—Kaczmarek v. Geuder, Paeschke & Frey Co., Wisconsin Supreme Court, 134 N. W. 348.

Expert Evidence—Subjective and Objective Symptoms—Basis of Opinion on Proved Facts.—The rule is well settled that where a physician has been called to professionally treat a party to an action he may give his opinion, based upon subjective as well as objective symptoms. But where he has been called, not for the purpose of treating the party for the ailment, but for the purpose of giving testimony in the case, he can only testify to objective symptoms. Statements made by the plaintiff at such examination are mere self-serving declarations, not made upon oath. Evidence, therefore, consisting of the opinion of such physician based upon what the plaintiff told him at the time of the examination relative to his previous history and how the injury occurred is not admissible.

In an action for personal injuries the plaintiff testified that on the evening of the injury he noticed that his abdomen was a little bit puffed up, but that it did not swell up enough to make much difference in his size until about the fifth or sixth day after the injury. Nothing in the testimony indicated that within 24 hours after the accident the abdomen was in a badly swollen condition. A hypothetical question, however, was put to an expert medical witness, assuming that immediately after the accident, severe and intense pains were present in the plaintiff's abdomen, in the region of the liver; that the abdomen began to swell so that within 24 hours it was in a badly swollen condition, and within about two weeks from the injury it became hardened and continued in that condition. It was held that the question was improper, under the rule that a hypothetical question should not embrace facts not in the evidence.—Union Pac. R. Co. v. McNucan, Circuit Court of Appeals, 194 Fed., 393.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

POLYZYTHÄMIE UND PLETHORA. By HANS HIRSCHFELD. 54 pages; illustrated; paper; Vol. IV, No. 2; price $1.50 M. Carl Marhold, Publisher, Halle.

TUBERKULOSE-ARBEITEN AUS DEM KAISERLICHEN GESUNDHEITSAMTE. No. 13. Edited by Dr. HAMEL. 124 pages; paper. Julius Springer, Publisher, Berlin.

DIAGNOSE DER SIMULATION NERVÖSER SYMPTOME. By Dr. SIEGMUND ERBEN. 194 pages; illustrated; paper; price $2.15. Urban & Schwarzenberg, Publishers, Berlin and Wien.

DER PRIMÄRE LUNGENHERD BEI DER TUBERKULOSE DER KINDER. By Dr. ANTON GHON. 141 pages; illustrated; paper; price $2.15. Urban & Schwarzenberg, Publishers, Berlin and Wien.

DIE PHYSIKALISCHE THERAPIE DER GELENKKRANKHEITEN. By Dr. EDWARD WEISZ. 265 pages; illustrated; cloth; price $1.50. Urban & Schwarzenberg, Publishers, Berlin and Wien.

STOMATOLOGY IN GENERAL PRACTICE. By H. P. PICKERILL, M.D. 268 pages; illustrated; cloth. Oxford University Press, Publishers, New York.

MANUAL OF SURGERY. Vol. III. By ALEXIS THOMSON, F.R.C.S., and ALEXANDER MILES, F.R.C.S. 565 pages, with 220 illustrations; cloth. Oxford University Press, Publishers, New York.

TEXT BOOK FOR NURSES. By E. W. HEY GROVES, M.S., F.R.C.S., and J. M. FORTESCUE-BRICKDALE, M.A., M.D. 407 pages; illustrated; cloth. Oxford University Press, Publishers, New York.

THE SEXUAL LIFE OF THE CHILD. By Dr. ALBERT MOLL. 339 pages; cloth; price $1.75 net. The Macmillan Company, Publishers, New York.

INTERNATIONAL CLINICS. Vol. II, 22nd Series. Edited by HENRY W. CATTELL, A.M., M.D. 316 pages; illustrated; cloth; price $2.00. J. B. Lippincott Company, Publishers, Philadelphia.

PREVENTABLE CANCER. By ROLLO RUSSELL. 167 pages; cloth; price $1.50 net. Longmans, Green & Company, Publishers, New York.

THE ESSENTIALS OF MORBID HISTOLOGY. By ALBERT S. GRÜNBAUM, M.A., M.D., F.R.C.P., D.P.H. 219 pages, with 22 Colored Plates and 139 Other Illustrations; cloth; price $2.00 net. Longmans, Green & Company, Publishers, New York.

LEHRBUCH DER KRANKHEITEN DES SAÜGLINGS. By Dr. A. LESAGE and Prof. Dr. RUDOLF FISCHL. 696 pages; illustrated; paper; price 12 M. Georg Thieme, Publisher, Leipzig.

PLASTISCHE OPERATIONEN. By Prof. Dr. PH. BOCKENHEIMER. Vol. I. 160 pages; illustrated; paper; price 9 M. Curt Kabitzsch, Publisher, Wurzburg.

SALVARSAN IN SYPHILIS AND ALLIED DISEASES. By J. E. R. MCDONAGH, F.R.C.S. 152 pages; cloth. Oxford University Press, Publishers, New York.

LA STERILISATION DE LA SYPHILIS. By Dr. LEREDDE. 147 pages; paper; price 2 fr. 50. A. Maloine, Publisher, Paris.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. Held in Denver, Colo., June 19-22, 1911. 369 pages; illustrated; cloth. American Medico-Psychological Association, Publishers.

ESSAYS ON GENITOURINARY SUBJECTS. By J. BAYARD CLARK, M.D. 174 pages; cloth; price $1.25 net. William Wood & Company, Publishers, New York.

SEVENTEENTH REPORT OF THE BOARD OF HEALTH OF THE TOWN OF MONTCLAIR, NEW JERSEY. From Jan. 1, 1911, to Dec. 31, 1911. 86 pages; paper. Board of Health of the Town of Montclair, New Jersey, Publishers.

DIE GESUNDHEITSKONTROLLE DURCH DEN ORGANSINN. By Dr. ANTON BROSCH and Dr. OTTO VON AUFSCHNAITER. 67 pages; paper; price 2 M. Franz Deuticke, Publisher, Leipzig and Wien.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. Vol. IV. No. 3/4. By Drs. L. KATZ, H. PREYSING and F. BLUMENFELD. 159 pages; illustrated; paper; price 8.50 M. Curt Kabitzsch, Publisher, Wurzburg.

LEHRBUCH DER MILITÄRHYGIENE. Vol. IV. Edited by Prof. Dr. H. BISCHOFF, W. HOFFMANN and H. SCHWIENING. 515 pages; illustrated; paper; price 7 M. August Hirschwald, Publisher, Berlin.

Medical Items.

Sclerema Cutis (Adultorum).—J. Galloway reports the case of a man, aged fifty-four, who stated that his malady followed rapidly after he was exposed to a foul atmosphere, the unpleasant odor of which he found difficult to get rid of for an unusually long time. The hardening of the skin followed this incident, and progressed for the following three months. The firm, swollen state of the skin was noticeable from the face down to about the level of the loins, and was universal within this area, though worse in some parts than in others. It was especially noticeable round the neck, over the arms, and the skin of the back. The firm swelling of the skin impeded especially the movements of the neck, the shoulder, and elbow, and gave a peculiar expressionless appearance to the face. Some hardening of the skin had been noticed about the lower part of the thighs and knees, but had passed off On the trunk a certain degree of erythema could be noted where the hardening of the skin was greatest or most recent. On the inner aspect of the arms the hardening of the skin was seen to have a lobulated texture. There was no appearance of sclerodermia of the usual type nor of morphea at any part of the affected area. The distribution of the affection was practically continuous within the limits of the affected region. A careful physical examination had not revealed evidence of visceral disease, and had not suggested the cause of this unusual affection.—*Proceedings of the Royal Society of Medicine.*

Esophagus with Perforations Due to Ulceration Produced by Foreign Bodies.—A. B. Kelly reports the case of an imbecile lad, aged sixteen, from whom a coherent statement could not be obtained, but who was suspected of having swallowed a foreign body. The medical man consulted examined him with the *x*-rays, but finding nothing abnormal prescribed a purgative, with the result that a dozen acorns were passed. As marked inability to swallow persisted, the patient was sent to the author about two weeks after the supposed accident for examination of the esophagus. At the lower end of Brünings' longest tube when fully introduced a foreign body was encountered; and lying above it were two peas. The body itself was firmly embedded in the posterior wall of the gullet, and the surrounding mucous membrane presented many granulations. After considerable trouble the body, which proved to be another acorn, was broken up and removed piecemeal. Beneath it a large part of a vertebra, possibly that of a sheep, was found and comparatively easily extracted. As a perforation into the trachea had been detected before operation no food was given by the mouth. In spite of this precaution and efforts to keep the parts clean the patient died a week later. The post-mortem examination revealed multiple abscesses and gangrene of the lungs. The esophagus showed five perforations in the posterior wall, where ulceration had extended to the underlying vertebral column, and one in the anterior wall communicating with the trachea.—*Proceedings of the Royal Society of Medicine.*

Radium Treatment of Vegetating Epithelioma of the Cervix Uteri, Primary and Recurrent.—H. Cheron and H. Rubens-Duval make use of radium in massive doses in the treatment of vegetating cervical epithelioma, as a curative measure. The characteristics of these cancers are soft, friable masses, with large, weak-walled vessels, which easily break and cause severe hemorrhages. These cells are peculiarly sensitive to the radium rays. The tumors do not at first infiltrate and glandular metastases are a late development. The radium is used with careful filtration so as to avoid superficial burns of the vagina, the gamma and the beta rays being used. The application must last 24 or 48 hours; a previous curetting may be an advantage, since it removes a great deal of friable tissue. It destroys the nutrition of the cells and scleroses the blood vessels, finally obliterating them. The hemorrhage and pain are at once relieved, and the patient regains a fair physical condition. These cancers are very unfavorable to operation on account of their rapid recurrence. When a hysterectomy is to be done a previous application of radium and curetting will stop hemorrhage, and remove infected material, and the tissues will be somewhat hardened and thus facilitate the removal. If too much radium is applied it will render the tissues so dense that removal will be very difficult. In cases in which the parauterine tissues are much involved operation is contraindicated, and here radium has a clear field; also in recurrences after operation. The vagina becomes sclerosed and contracted. A severe dermatitis may be caused if the rays are not carefully filtered.—*La Gynécologie.*

SANATORIUM TREATMENT OF TUBERCULOSIS.*

By LEROY S. PETERS, M.D.,

AND

E. S. BULLOCK, M.D.,

SILVER CITY, N. M.

IT is not with a desire to thrust upon the world a new specific for tuberculosis that we have chosen the above title, but rather to discuss a few unique methods in the every-day routine of sanatorium practice. To cover the treatment of this disease would mean to give page after page of uninteresting textbook knowledge which is of easy access to him who reads, and which is equally as valueless as it is uninteresting. We use the term valueless in a general sense, for the true success of treatment lies in the mental equipment and the personal equation of the physician himself. This latter is a fact well recognized by all men who have as their life work the care and treatment of tuberculous invalids.

And herein lies the great value of sanatorium over home treatment. In a disease that measures its arrest or cure in months or years rather than days or weeks this same personal equation of the physician is over half the battle. Nor is this secured in the home where as a rule the visits of the physician are semi-weekly, but in an institution where the doctor and patient are in almost constant contact, and where, if necessary, the calls may be made hourly and at any minute, and the spirit of encouragement lent that makes or breaks the thread by which a human life is held. The right word at the right time will perhaps do more toward the cure of tuberculosis than all other means combined.

But enough of generalities—the world is full of them—and the busy physician has neither time nor inclination to pore over volumes or lend ear to papers that embody a jumble of words and are woefully lacking in ideas.

The factors in the treatment of tuberculosis to which we shall refer may be thus stated: Climate, hypodermics of iron, arsenic, and strychnine in the secondary anemias of tuberculosis; the use of salvarsan in cases complicated with syphilis; treatment of cases with marked hemorrhage from the bowel; blood pressure control of exercise; injection of intestinal hormones in the chronic constipation of the tuberculous; autogenous vaccines; tuberculin.

Climate.—We deem it a great pleasure to feel that what we may say before a State meeting in Arizona on the subject of climate will at least meet with the approval of the vast majority. However, we realize that the variations of altitude in your State are many and for this reason some difference of opinion may exist. Years ago, before we realized that tuberculosis might become arrested under proper conditions, the far advanced consumptive was advised to go West, and this with no idea as to locality, mode of living or what not—merely to chase a will o' the wisp in a vain endeavor to put new lungs into a shrunken chest and create again in a worn out body the breath of life. Climatic treatment was then an empiricism; to-day it is a scientific fact.

And here let us digress long enough to state that we are firmly convinced that the greatest value of any climate lies in its elevation. In other words, the question of climate is a question of altitude. It must of course be granted that change of environment of necessity makes for a betterment in the general condition. Move a consumptive from the slums and tenements of a large city to a country place, change his diet from one of starvation to one of nourishment, and he is bound by all laws of nature to improve. Change a city dweller in good circumstances to the Adirondacks and you may arrest his tuberculosis, but to give the greatest good to the greatest number move all consumptives to the altitudes of the Rocky Mountains—then keep them there—and in a time not far distant the deaths from tuberculosis will be reduced to a minimum. These are not dogmatic statements; they are not mere flights of the imagination. The climatic treatment of tuberculosis has been established as a scientific fact by scientific observations made in the past few years by altitude workers.

In the first place that climate depends more upon altitude than upon dry air and sunshine is proven by a comparison of statistics in well conducted institutions in this country and abroad. Without here going into figures we have found by a careful study of sanatorium reports in the United States that the percentage of cures increases with each thousand feet of altitude up to certain limits. Is such a fact not in itself significant? Further, comparing our own work with that of Turban in Davos Platz at practically the same altitude, we get results that are almost identical. This then must be attributed to altitude, since government reports show that the climate of Davos Platz is colder in winter with greater snowfall and a more marked degree of humidity in summer than is the climate of Silver City.

It has also been demonstrated by Williams, of London,[1] that there is a marked expansion of the thorax in all directions, causing an increase in circumference at various levels of from one to three inches or more, and an increased mobility of the chest walls. This causes a greater physiological activity of the lungs, thereby insuring a greater amount of oxygen content in the blood.

Webb and Williams[2] have proved that with residence in a high altitude the lymphocytes of the blood are increased to a marked extent. These, as

*Read at the annual meeting of the Arizona State Medical Association, Bisbee, May 7, 1912.

you know, are the white cells that Doctor Opie, of the Rockefeller Institute, proved to have the ability to dissolve the waxy coating of the tubercle bacillus and then through a process of digestion destroy the invading organism, thereby ridding the body of a most obnoxious guest. We have confirmed the work of Webb and Williams in our blood studies at The New Mexico Cottage Sanatorium. That the hemoglobin content of the blood is increased with altitude has been a recognized fact for years, but it remained for an English commission working with American collaborators to prove that this was actual—not relative—and that the red cells were increased as high as 40 per cent. These observations were made in the Swiss Alps and in our own Rocky Mountains at elevations of from 6,000 to 14,000 feet.

In 1907 one of us (Peters) began the study of blood pressure at high elevations (6,000 feet) and the first results of our work was published in 1908,[3] covering a series of one hundred cases. The conclusions reached at that time were the subject of some comment since they were in direct contradiction to the excellent work of Gardiner and Hoagland.[4] However, after working along the same line for another period of four years we do not find it necessary to retract any of the statements made at that time. We are now preparing another report covering about six hundred cases, from which we draw the following conclusions:

1. Blood pressure is increased at elevations of 6,000 feet.

2. The pressure of both normal individuals and consumptives is higher here than at sea level.

3. The pressure tends to increase with continued residence.

4. From a prognostic standpoint the blood pressure findings are of great value in tuberculosis.

5. There is no relation between the degree of involvement and blood pressure, but there is a constant relation between toxemia and blood pressure.

6. The pressure is increased with pulmonary hemorrhage.

The various factors herein enumerated relative to altitude all tend toward the betterment of metabolism and the continual restoration of the body economy toward the normal; factors which must of necessity play an important rôle in the cure of tuberculosis. Thus has climatic treatment been torn from the realm of uncertainty and placed upon a sound scientific basis.

Hypodermics of Iron, Arsenic, and Strychnine in the Secondary Anemia of Tuberculosis.—It is generally conceded that there is a certain autolysis of blood elements in tuberculosis and constant hemoglobin estimations and blood counts bear this out. In nearly every case there is a secondary anemia of greater or lesser degree according to the severity of the infection. Any treatment that tends to remedy this condition is therefore rational and deserving of general use. In the hypodermic injection of iron, arsenic, and strychnine we have a combination that is specific in the treatment of this secondary anemia. Added to its ability to restore the hemoglobin content it acts as a general tonic, and according to W. Jarvis Barlow[5] is a remedy that proves useful in every case of tuberculosis regardless of the presence of anemia.

We reported our first observations in 1908,[6] and in 1911 read a paper before the National Association for the Study and Prevention of Tuberculosis at the Denver meeting. In this report we gave the results in a series of 254 cases in all of which marked improvement followed the injections. Our usual method is to give a daily injection in the gluteal region for twenty consecutive days. Almost invariably, unless there is marked anemia, we find this sufficient to restore a normal blood picture. Since the publication of Barlow's paper we have been giving the injections to every patient and are willing to state that clinically at least the results are satisfactory, patients feeling far better than when the drug is discontinued.

Our conclusions may be summed up as follows:

1. The injections are specific in the secondary anemia of tuberculosis.

2. The citrate of iron alone is best suited in marked anemia.

3. The metarsenate of sodium, iron, and strychnine is the best as a general tonic.

4. Arsenic and strychnine tend to promote better metabolism.

5. The hypodermic use of these drugs should always have a place in the treatment of tuberculosis.

Use of Salvarsan in Cases with History of Syphilis.—It has been our custom during the past nine months to administer salvarsan to all patients showing a recent syphilitic infection or to those not doing well but having a history of syphilis. There is no question but that there is a much greater amount of syphilis of the lung than heretofore has been supposed, and in these patients it is hard to say just how much of their trouble is specific and how much tuberculous. It is not at all uncommon for us to find that all we can do in a given case is of no avail until we have given an injection of "606," when we are gratified to see the pulmonary symptoms grow better and the general condition improve. Appetite is increased, cough and expectoration lessened, and fever reduced in a wonderfully short space of time.

In the patients thus far to whom we have given salvarsan we have had no untoward symptoms—with one exception. In this patient the temperature rose about three hours after the injection and he was slightly delirious for a period of four hours. From then on the recovery was uneventful. We use nothing but the intravenous method and prepare the distilled water and the normal salt solution the morning of the day on which the injection is given. This eliminates the possibility of the formation of any foreign proteid in the water or salt solution which in itself might produce annoying symptoms.

We feel justified from our experience in recommending the use of salvarsan in all cases with recent syphilitic infection, or in all those with a specific history who are not doing well under the ordinary methods of treatment. It is, of course, unnecessary to mention that as a matter of routine the urine of each patient should be examined and the reflexes tested with a view to excluding kidney disease or lesion of the central nervous system.

Treatment of Marked Hemorrhage from the Bowel.—This is a condition seldom met with in cases of tuberculosis. In fact, as our report[7] some months ago shows, we have had only three cases in an experience covering fifteen years, while Dr. Bonney reports two cases over a period of twenty years. Since the publication of these five cases we have received a report of one case from Dr. Shortle of Albuquerque, New Mexico; one from Dr. Lauzer of Rock Springs, Wyoming, and one from Drs. Shuman and James of Centerville, Iowa. In these

eight cases the bleeding was profuse and in four fatal, the other four making good recoveries. We have no explanation for these hemorrhages, but see no reason why they should not occur from tuberculous ulceration of the intestine, as they do in typhoid ulceration. They may, however, be due to a pneumococcus infection of the intestinal tract as pointed out by Jacobson and Post.[8] The treatment we have used is absolute rest, liquid diet, hypodermics of morphine, ¼ grain at time of the hemorrhage followed by opium suppositories every two hours pushed to the point of therapeutic effect. For a more complete report we refer you to the article above cited.

Blood Pressure Control of Exercise.—It has been generally conceded that after severe athletic tests the blood pressure is reduced sometimes to a marked degree. This has recently been the subject of an able paper by Otis[9] read before the American Climatological Association at its last annual meeting. It occurred to one of us (Peters) that if such a reduction could be demonstrated in normal individuals after fatigue this same factor might be of great importance in controlling the exercise of consumptives. With this in view a class of six men was selected, three being excellent cases both pulmonarily and physically; two fairly arrested far advanced cases, and one a rather new recruit with normal temperature but physically inferior.

All were started with a fifteen minutes walk the first day. The pressures on starting of the three able-bodied men were 138, 132, and 148 respectively. On their return the pressures were 138, 144, and 153. After an hour's rest the readings were 138, 142, and 158, showing that apparently the exercise was not harmful. The two fairly well arrested, far advanced cases, started with pressures of 164 and 124, returning with 146 and 130, and after resting, 164 and 118. The first man was not used to exercise in any form, as is well shown in a drop of 18 millimeters of mercury with a return to the original after an hour's rest. The overexertion in the second man is evident, for we find after resting that there is a drop of 6 millimeters from the original reading recorded after the return from exercise.

The new recruit started with 146, returned with 138, and after rest his reading was 127. The overexertion in this instance is well illustrated from the pressure findings and was further substantiated by the marked fatigue, breathlessness, and rapid heart action of the individual himself. This experience was carried on for a period of six days, each day's exercise being graded by the previous day's results in blood pressure. The table of these findings which we here append will show you at a glance that we were able to control the readings by an increase, a decrease, or a repetition of the exercise. Whenever a man showed a drop of 6 or more millimeters of mercury after rest or a marked drop on returning, even though this disappeared after resting, we decreased the exercise. If there was a slight drop after returning we repeated the same exercise the following day or until we maintained an even standard, when the walk was increased. It is interesting to note that in one of the three excellent cases the pressure remained practically the same even up to walks of one and a half hours, and later this same man took walks of two hours in the morning and two in the afternoon with no change in pressure and no evil results. The other two after a few repetitions were able to do the same.

We believe that this observation will prove of great value in controlling the exercise of consumptives since it is not always a safe procedure to rely wholly upon pulse and temperature.

The Use of Intestinal Hormones in the Chronic Constipation of the Tuberculous.—Recently it has been demonstrated that the cells of the mucous membrane of the stomach elaborate a so-called hormone which has a marked effect on peristalsis. This hormone is secreted in the antrum pylori and

stored in the spleen. When absorbed it causes a secretion of the normal gastric juice. Working on this hypothesis Zuelzer[10] has studied the peristaltic hormone for therapeutic purposes. He has used it in chronic constipation and in acute paralysis of the intestine, with excellent results, so he states, in 71 per cent. of his cases. Its use in spastic constipation is, of course, contraindicated since here we have an over stimulation of the intestine.

In the constipation of the tuberculous we have as a causative factor the faulty secretion of the gastric juice, as is evidenced by a lack of free hydrochloric acid. Naturally, when we can introduce a remedy that tends toward the production of a normal secretion and thus stimulates peristalsis we should from the standpoint of theory at least cure the constipation. Working on this basis we have been injecting intestinal hormones in doses of 20 c.c. both intravenously and intramuscularly. Contrary to the literature on the subject we find that intramuscular injections are not painful and of course are much more easily given. There is always more or less nausea following an injection, and a feeling of discomfort for a period of twenty-four hours. Since we find no ill effects following an intramuscular injection we use that method as a matter of routine. Our results so far in a limited number of cases have been sufficiently satisfactory to encourage us in its use.

Autogenous Vaccines.—For the past three years we have continually used autogenous vaccines in all cases of tuberculosis showing a daily range of fever above 101° Fahr. Lately we have been giving them in all cases with a temperature curve over 100° Fahr. Like tuberculin one cannot look for wonderful results in the use of these vaccines, and it has occurred to us that perhaps the reason we have not perceived more striking curative effects lies in the fact that until recently we have chosen the most unlikely cases from the standpoint of cure. It is a fact that cannot be made light of that to expect to cure hopeless cases of tuberculosis with any given drug or serum is looking forward to the intervention of a divine Providence. For that reason we have made it a matter of routine to first employ an autogenous vaccine in all patients with a fever above 100° Fahr. Then if we get no appreciable result we begin the administration of tuberculin, using the one in conjunction with the other.

So far our results have been such as to justify us in a continuation of this form of treatment, and, clinically speaking, we feel that there is much of good to be derived from the application of Wright's theories of vaccine therapy. To sit idly by and dogmatically declare that a patient does as well without such medication as with it is to put a spike in the wheels of progress toward scientific medicine which in our opinion is nothing short of criminal. Careful administration of such vaccines and personal supervision of patients eliminates all danger from such procedures, and the wonderful improvement in many patients after their use is proof positive of their beneficial effects.

We make the vaccines in our own laboratory and give the injections at weekly intervals, starting with an average dose of one hundred million dead bacteria and gradually increasing the dose unless contraindicated. The length of time of treatment is guided entirely by results, some patients taking injections for as long as eighteen months.

Granting, as we all do, that much of the fever in tuberculosis is of mixed infection origin, why is it not rational to use methods of treatment directed at the causative factors? Theoretically the use of autogenous vaccines and tuberculin is the one scientific principle in the therapy of tuberculosis.

Tuberculin.—In a paper of this nature space does not permit a full discussion of the experimental and theoretical knowledge of tuberculin therapy. That we have done in a paper to be read at the next annual meeting of the Harper Hospital Alumni Association at Detroit, Mich., in May. Here we shall confine ourselves to a consideration of the application of tuberculin in the treatment of tuberculosis.

We realize that probably no therapeutic measure has more firm adherents nor more sworn enemies. Those of us who have had a large experience in its use and have seen wonderful examples of its undoubted effect are firmly convinced that it holds a scientific place in the armamentarium of every tuberculosis worker. On the other hand, those who have never used it and who declare dogmatically against its application to the therapy of tuberculosis are either ignorant of its field of usefulness or are wilfully neglecting a valuable agent in the treatment of a disease that is otherwise almost hopeless from a direct therapeutic standpoint. To condemn a given remedy because of reckless use on its introduction into the field of medicine, or to neglect to use it because of a foolishly conceived idea that it might do harm in some cases is absurd.

In our opinion every physician who has the care of tuberculous invalids should feel free to use tuberculin and should so acquaint himself with its use that he may judge wisely in selecting patients and in administering the remedy. It is not now as in the past a measure for the specialist or the sanatorium worker. Time has modified the technique and experience has taught us the fallacy of high doses, so that any conscientious physician can with a little time and trouble work out to his own satisfaction and that of others a sound basis for the administration of tuberculin.

Roughly speaking, tuberculin can be given to the large majority of consumptives, but that we see an appreciable effect in all patients does not necessarily follow.

First, there are those who accept every injection as though it were a dose of distilled water and a so-called course up to a thousand milligrams may be given without the slightest systemic disturbance. From a prognostic standpoint this class forms the most favorable of all tuberculous invalids, and there is little doubt that nature has conferred upon them, before the use of tuberculin, a toxic immunity so that the additional tuberculin is superfluous and in our opinion productive of neither good nor ill.

Second, there is a small class with the most unfavorable prognosis who develop a marked hypersusceptibility and in whom all toxic symptoms are exaggerated by tuberculin. There is little doubt but that in these patients tuberculin therapy is harmful if persisted in, but if withdrawn at the first signal of distress evil results will not follow.

Third, there is a class in which tuberculin is unequivocally beneficial. For the sake of clearness we shall divide this class into those with fever, limiting such temperature to averages below 101° Fahr.; those showing marked improvement following reaction, and those showing a general but slow benefit.

In the fever cases just mentioned showing a temperature curve from 99° to 101° tuberculin is the most efficient measure at our command and often

succeeds when complete immobilization has failed. Although reactions should be guarded against, at times they occur and everyone no doubt recalls the marked improvement and sometimes cure following such overdosage.

We have patients under our care for the past six years who continue to live in comfort and enjoy life while under tuberculin treatment, but the moment it is stopped general malaise and discomfort follow together with an increase in the pulmonary findings. Resume treatment and a return to former feeling of well being ensues. A large number of patients show this same general but slow improvement under tuberculin and progress steadily toward an arrest or cure, which we feel confident would not have been possible without the use of this measure.

Do not form the opinion that we give tuberculin to everybody—that we do not. When a patient enters the institution we give him an opportunity to see what nature will or will not do. Tuberculin is not considered until we have learned the individual, his powers of resistance, what he will do for himself. In this way we are better able to form honest opinions as to the value of the tuberculin, and in patients who show a marked ability to recover under ordinary measures we do not interfere.

To use tuberculin requires a certain amount of care and common sense. We mention the use of the reaction method in guiding dosage merely to condemn it. Although we have seen brilliant results follow the administration of an overdose, we know positively that once started a reaction is uncontrollable and is capable of far greater injury to the organism than would be justified by an occasional brilliant result.

The so-called scientific method of White and Norman is worthy of mention. These men have demonstrated that by using the smallest amount of tuberculin that will produce a minimum skin reaction and then taking a division of this amount for subcutaneous injection the proper dose for each and every case has been supplied. The method is attractive but too new a procedure upon which to pass judgment. For the present the clinical method advocated by Trudeau seems more rational and deserving of common use.

The opsonic index is not reliable and if we are to accept the theory of Jackson and Hawn[11] what we once considered an expression of the immune process is simply a matter of surface tension of leucocytes and can be influenced at will by a concentration or a dilution of the blood current. Experience has shown us that with such preparations as B. F. and B. E. the initial dose as recommended by Trudeau is much too high. In fever cases we start with one ten millionth of a milligram and have seen undoubted reactions occur with nine ten millionths.

One of us (Bullock) has developed a modification of the clinical method which we feel sure is a long step in advance in tuberculin administration. This method was first proposed at the Los Angeles meeting of the American Medical Association in 1911. As far as we know, no attention has been given it by American observers, and it has been very gratifying to have the usefulness of the method confirmed by so able a clinician as Eduard Bauer.[12] Bauer is evidently not aware that we had already developed and published this method. We trust that this will not be interpreted as a claim to priority, in which we have no interest, but simply an acknowledgment of our satisfaction in his confirmation of the method.

Briefly this procedure which we have practised at our institution for the past three years may be described as maintenance of an effective dose in either febrile or afebrile cases, and raising the dose when it has become enfeebled by repetition as confirmed by absence of clinical effect. Let us give a practical illustration. A patient exhibits a persistent maximum temperature of 99.3° Fahr. The dose is gradually raised until an effective point is reached, one which reduces the temperature. This dose is then repeated until a rise again occurs, when the dose is not lowered but raised, following the temperature up as it were in an attempt to again reach an effective dose until gradually the temperature drops to and is maintained at normal. This fortunate result having been observed we are guided in the dosage by principles which obtain in normal temperature cases in which general clinical effect is our guide for repeating or raising the dose. We trust that we have made it perfectly clear that no attempt is made to reach a high dose during any period of the treatment.

In the foregoing we have tried in as brief a manner as is consistent with clearness to outline a few of the usual as well as unusual measures in the treatment of tuberculosis. We trust they will at least receive your consideration and that you will be able either to refute or verify our work.

OBSERVATIONS FROM 300 CASES TREATED BY AUTOGENOUS BACTERIAL VACCINES.*

By HENRY A. CRAIG, M.D.,

NEW BRIGHTON, NEW YORK.

PATHOLOGIST AND BACTERIOLOGIST, S. R. SMITH INFIRMARY; BACTERIOLOGIST, ST. VINCENT'S HOSPITAL, STATEN ISLAND.

Bacterial vaccines consist of a suspension of bacteria in normal salt solution, killed by heat or chemicals, and standardized by enumeration and dilution so that each cubic centimeter contains a convenient number of bacteria, varying according to the dose of the particular vaccine. A preservative is added to prevent contamination, such as carbolic ½ per cent.

Autogenous vaccines are made from the bacteria obtained from the patient under treatment and therefore must correspond to the bacteria causing the disease. Stock vaccines consist of bacteria morphologically similar to those causing the disease but obtained from some other source than the patient under treatment. Unfortunately, being

*Read before the Medical Association of the Greater City of New York, June 10, 1912.

morphologically similar does not guarantee that they will correspond exactly to the basteria at fault, for the reason that many of the great groups of bacteria have a large number of subdivisions, *e.g.*, the streptococcus and the colon bacillus. Hence autogenous vaccines, if available, are, in every case, superior to stock vaccines. Infections are very apt to be mixed, so in making an autogenous vaccine it is wise, in many cases, not to isolate any particular organism but to grow all together synergistically and to standardize this vaccine according to the predominating organism. Less than two-thirds of the present series were due to infection by a single organism, in the other one-third of the cases, two or more organisms being found. Also, in chronic infections, a change in the bacterial flora is apt to take place, the original infection dying out and another bacterial infection taking its place or being added to it; so that it is necessary to make new cultures from time to time in order to recognize any change in the bacterial flora and make a new autogenous vaccine when necessary.

The purpose of bacterial vaccines is to assist nature to produce an active immunity against the infection present. Before the use of sera and vaccines in the treatment of disease, we had to wait for the body to manufacture the necessary antibodies to neutralize the toxin and destroy the bacteria causing the disease. When this is delayed, we have a prolonged illness or a fatal ending due to damage to some vital part. The early use of bacterial vaccines stimulates the tissues to form the proper antibodies and this saves the tissues from the prolonged harmful influence of the toxins and bacteria. In other words, the keynote of the treatment of all bacterial infections is the production of immunity. Which means the power through which a cure is effected as well as the power to resist infection.

Immunity is of two forms, active and passive. The injection of the various sera produces passive immunity, for the protective agencies are introduced into the body all ready for action against the toxins or bacteria. This would seem an ideal method of treatment, for the immunity produced is almost immediate and requires no effort on the part of the body. Unfortunately the immunity produced is but temporary and the treatment has but a narrow application. It is possible to produce sera antagonistic to the bacterial causes of disease in only a few instances, notably diphtheria, tetanus, etc.

The immunity produced by the introduction of bacterial vaccines is an example of active immunity. The body tissues are stimulated to produce their own protective agencies, the same as occurs in the case of natural recovery from an infection. This treatment has a very wide applicability, in every case in which the causative organism can be obtained or is known.

This treatment necessitates sufficient vitality on the part of the body to respond to the stimulus of the vaccines. In case the body is too exhausted by toxemia, etc., the tissues lose their ability to respond to the stimulus of the vaccines by elaborating the specific antibodies. Hence the treatment should not be left as a last resort when the body has neither the time nor the ability to react. In such cases the sera, if applicable, would promise more, attempting to produce passive immunity which would require neither time nor effort on the part of the body.

Infectious diseases are due to the entrance within the body of some kind of bacteria. If the body is susceptible to their injurious effects, it resists the invading hosts and a fight to the death of one or the other is on. The bacteria multiply rapidly, either locally or generally, and produce their harmful effects chiefly by the elaboration of poisonous toxins. In this battle between the body and the bacteria, the body's principal method of defense is by means of the phagocytes (cells having the power of engulfing or ingesting the bacteria and destroying them by a process of digestion). Many of the cells of the body have this power, but the principal phagocytes of the body are the white blood cells. These are the soldiers of the body, a great standing army, able to be doubled or tripled at a short notice. But these soldiers are helpless without the proper weapons. The necessary weapons are substances in the blood serum called opsonins, so called because they so act upon the bacteria that the latter are easily taken up by the phagocytes and destroyed. They do not act by stimulating the phagocytes to increased activity as might be supposed. If an emulsion of bacteria and one of washed leucocytes are put into a test tube together, nothing happens. Then add some fresh blood serum which contains the necessary opsonins and the leucocytes vigorously attack the bacteria.

The result of the administration of bacterial vaccines is to increase the specific opsonins. This can actually be measured by taking the opsonic index, which is the measure of the opsonic power of the blood serum of a patient as compared to the normal. It also increases the leucocytes, thus increasing the soldiers as well as their weapons. It must be remembered that the administration of bacterial vaccines does not directly furnish the soldiers, phagocytes, with the necessary weapons, opsonins. It simply stimulates the body tissues and especially the subcutaneous connective tissues to manufacture more of the needed opsonins. Therefore bacterial vaccines are never given intravenously or by mouth but by hypodermic injection into the subcutaneous connective tissue, where the opsonins are principally elaborated, absorbed by the blood, taken to the site of the infection, if it is a local one, and assist the phagocytes in their fight at this point. In this we are simply copying nature, for in any infection many of the bacteria are killed and disintegrated, acting then as an antigen to increase the specific opsonins, just as the absorption of toxins from the site of infection stimulates the body to produce antitoxins, etc.

After the administration of bacterial vaccines the opsonins increase in amount for approximately ten days, when the maximum is reached. Then they remain constant for a time and then slowly decrease to the normal after a period of weeks or months. In many diseases the immunity produced lasts much longer than the period of time during which antibodies are found in the blood. This is due, no doubt, to the fact that the tissues acquire the power of reacting quickly to the same infection in case it subsequently occurs, so that large amounts of antibodies are quickly elaborated and the invading organisms destroyed before they accomplish any injury.

Why are autogenous vaccines superior to the stock vaccines? Just as antitoxins, precipitins, agglutinins, anaphylactins, etc., have been shown to be absolutely specific, so the opsonins produced by the injection of bacterial vaccines are absolutely specific, preparing only that particular variety of

bacteria for ingestion by the phagocytes. Therefore, unless the right vaccine is introduced, little or no good can be expected. It is not sufficient to have the right group of bacteria, but even the subdivision must correspond, as they are specific to that extent. To obviate this many of the stock vaccines are made from bacteria obtained from many sources—polyvalent vaccines. Also it is necessary to have a vaccine prepared from bacteria of the same virulence as those causing the infection. We could not expect much benefit from a vaccine prepared from an acne pustule in the treatment of a virulent carbuncle, though the infection in both cases might be due to the staphylococcus. These conditions can be perfectly fulfilled only by using an autogenous vaccine.

In the present series of cases the writer has made no attempt to measure the effects of the vaccine by taking the opsonic index. The technique is too elaborate and the results vary too much to justify the time and labor required. Clinical symptoms plus the aid of general rules afford a sufficient guide as to dosage, intervals between doses, etc. Taking the leucocyte count would not help any as a guide. Bacterial vaccines do, of course, increase the number of leucocytes in many cases. But there are many other things that do the same, as exercise, food, the cold bath, saline infusion, certain drugs, etc. As stated before, the value of the administration of a bacterial vaccine lies in its ability to stimulate the increased production of specific opsonins, thus furnishing the soldiers with the proper weapons for the fight. There are generally plenty of the soldiers, ten to thirty thousand per cubic millimeter—one to two million per drop—but if they are not properly armed they are powerless. In many infections in which the body seems to be getting the worst of the contest, this is the trouble, as proved by the good results following the use of vaccines. In typhoid fever the endothelial cells of the lymph spaces, etc., seem to be the phagocytes most active against this particular form of infection and the leucocytes are not increased. In tuberculosis the lymphocytes and connective tissue cells seem to bear the brunt of the defense, and again the leucocytes are not increased. But the opsonins are necessary in every case to act upon the bacteria in such a way that the phagocytes are able to destroy them.

The cases mentioned in this paper are by no means picked cases. They include all that came along in hospital, dispensary, and private practice. In fact, in the hospitals only the worst cases are, in many instances, turned over for this treatment. Some of the cases were not applicable for the treatment, but it was used as a last resort. Four patients died before a vaccine could be made, within twenty-four hours, showing the hopelessness of some cases for any treatment. A number died within a few days after the treatment was instituted before it could have any effect. If only applicable cases were picked for the treatment the results would look better. Besides these cases the writer has treated about a hundred cases with stock vaccines with good results in many instances, but these are not included in this report.

The best results were obtained in cases of staphylococcus infections. For staphylococcus infections the treatment is practically a specific. Seventy-one of the present series of cases were cases of pure staphylococcus infection. All were quickly cured except two hopeless cases of septicemia following osteomyelitis, making the mortality of this class of cases 3 per cent. This is the reason why carbuncles, furuncles, etc., even in diabetics, are so easily controlled, because they are generally pure staphylococcus infections. Also cases of cellulitis and of infections of any kind, when due to the staphylococcus, are generally quickly brought under control. In preparing a vaccine one is always glad to see it turn out to be a pure staphylococcus infection, for that means a good prognosis, as a rule, no matter how severe the infection.

Many infections, cases of cellulitis, abscesses, etc., are due to a mixture of staphylococcus and some other organism, very often the streptococcus. This means a more serious infection and more difficult to control. Sixty-one of the present series were cases of mixed staphylococcus and streptococcus infection. Three of them died—a mortality of 5 per cent.

The pure streptococcus infections are worse still—46 cases, 4 deaths; mortality, 9 per cent. Pure colon infections, 36 cases, 2 deaths; mortality, 5½ per cent. Colon infections, as a rule, are very amenable to treatment by autogenous vaccines, nearly as much so as staphylococcus infections.

The *Bacillus pyocyaneus* is said to be of such low virulence that a vaccine of this organism does little or no good. Still, six cases of this series due to *Bacillus pyocyaneus* responded very nicely to an autogenous vaccine. However, the number is too small to form an opinion.

Furunculosis, 15 cases. All were due to the staphylococcus except one that was due to a mixed staphylococcus and streptococcus infection, of long standing, and very intractable to all sorts of treatment. It yielded at last to autogenous vaccine treatment. All the others were quickly cured. No failures. Generally two or three doses are sufficient.

Carbuncles, 13 cases, 3 of them in diabetics. All were pure staphylococcus infections, and the results, in every case, should persuade the most skeptical of the value of the treatment. One, situated in the middle of the patient's back, was as large as a saucer and had about a dozen small openings. Another on the back of the neck in a diabetic with a purulent cellulitis reaching as far as the eyebrows, the whole scalp a boggy, purulent mass. No matter how severe, they quickly responded to the treatment. Very often the patients describe a difference in their general feelings a few hours after the first dose. It is only necessary to make a slight opening to let out the pus and detritus. No such enormous incisions and excisions, as were formerly necessary.

Cellulitis, 54 cases, involving hands, arms, legs, etc.; 23 were staphylococcus, 10 pure streptococcus, the others mixed infections. Some of them were very severe: temperature 105°. There were no failures. The staphylococcus cases yield the most readily, though some of the most brilliant results were in virulent streptococcus infections, where the patients were very sick, with high temperature, etc. Most of them were incised, but no such extensive incisions were made as would ordinarily be necessary to control the spread of the infection. This treatment, in conjunction with conservative surgery, is undoubtedly of great value in these cases, saving time, diminishing the danger of complications, and making unnecessary extensive mutilating operations.

Abscesses of various parts of the body, 23 cases: 5 staphylococcus, 2 streptococcus, 3 colon, the others mixed infections. The same observation holds here as for cellulitis. They require less extensive operations, heal more quickly, and there is less danger

of complications. The results were very satisfactory in every case. Several cases of ischiorectal abscess were in patients dying of tuberculosis. Even in these cases the treatment was worth while, diminishing the pain and discharge, and making the last days of the patients more comfortable. Ordinary ischiorectal abscesses are greatly benefited by the treatment.

Post-operative infections, 41 cases. These were nearly all the result of the trouble for which the operation was done and not following clean operations. Gangrenous or perforated appendix 20, pyosalpinx 9, gallstones or cholecystitis 3, hernia 5, ulcerating carcinoma of the breast 1, cesarian section, both infected before operation, 2; nephrectomy 1. Many of the cases were mixed infections—10 cases of staphylococcus, 9 of colon, and 2 of streptococcus, the others mixed. This is a class of cases in which the benefit from autogenous vaccines is very marked, shortening convalescence, diminishing the danger of complications, and assisting healing. All these cases were materially benefited. None died, though there were some severe cases of general peritonitis, etc.

General peritonitis, 10 cases; streptococcus, 2 cases of which 1 died, colon, 4 cases with 1 death, the others mixed streptococcus, colon, etc. All were desperate cases, were drained and received all the routine treatment. The low mortality of 20 per cent. is a remarkable result and looks as if the vaccine treatment helped out the operative interference.

Post-partum infections, 10 cases; staphylococcus 1, streptococcus 3, the others mixed streptococcus, staphylococcus, and colon. All were in a serious condition when treatment began, several seemed hopeless, but all recovered. This is a class of cases that can be materially benefited by autogenous vaccines, but the treatment should be started early before the patient is moribund from sepsis.

Post-abortion sepsis, 10 cases; seven were pure streptococcus infections, of which two died, the others mixed infections. Two had perforation of the uterus, one of them with damage to the intestines, both recovering. Of the deaths one lingered four weeks and died of exhaustion, the other of toxemia with a subnormal temperature. Apparently these cases are worse than cases of post-partum infections, streptococcus infections being more common, 7 out of 10 to 3 out of 10 of the latter.

Septicemia with positive blood cultures, 5 cases. One died, the writer's first case, a staphylococcus infection following osteomyelitis of the leg. The other three recovered—one colon, one staphylococcus, the other staphylococcus and streptococcus. Apparently the vaccine helped these three.

Septic endocarditis, 2 cases. Both died, one two days after the treatment was begun. Vaccine treatment is of no avail for such infections; the body is in no condition to manufacture its own protective agencies. Sera, if available, would be more apt to do good.

Erysipelas, 12 cases. One, a baby, died of exhaustion, a private case that the writer never saw, treated most of the time with a stock vaccine. The others cleared up with remarkable rapidity, the temperature rapidly becoming normal and the process soon being under control. The duration of treatment, according to many authorities, is cut in half, and apparently this is no exaggeration. In some cases it was not possible to get an autogenous vaccine, and they were treated with a polyvalent streptococcus vaccine with good results. The writer has failed to see any slowly spreading, long-drawn out cases treated by this method. The benefit which the patients feel twenty-four hours or so after the treatment is instituted is alone worth while, even if it did not cut short the disease, which it certainly does.

Pneumonia is a general infection with local expression in the lung, for the pneumococcus can be recovered from the blood in 70 per cent. or more of all cases. The general mortality, in spite of all treatment, remains high—20 to 25 per cent. (of 465,400 cases collected by Wells the mortality was 20.4 per cent.). There is preponderance of evidence that the immunity against pneumonia is a phagocytic one, therefore it would seem that the vaccine treatment should be especially applicable. It is essential that the treatment be instituted early. Time is a very necessary factor and there is little enough of it under the best of circumstances. There is no doubt that the treatment is applicable for pneumonia and of great benefit in many cases. Forty-seven cases of this series were cases of pneumonia with seven deaths; mortality 15 per cent. This does not give a fair idea of the value of the treatment, for many of the cases were turned over for the treatment as a last resort. Several died of delirium tremens, toxemia, etc., from 24 to 72 hours after the treatment was begun, and a number even died before the vaccine could be prepared. In proper cases, when the treatment is instituted early, it is very satisfying to see the toxemia diminished, the delirium clear up, the duration of the disease shortened, and convalescence more rapid. In an institution here on Staten Island for aged men (Sailors Snug Harbor), where the writer had early access to all cases of pneumonia, there was not a single death from pneumonia for a whole year, at one time, among nearly a thousand inmates. In the last 20 cases of pneumonia met with in the writer's private practice, treated with vaccine, there was but one death. Mortality 5 per cent. A stock vaccine should be administered while the autogenous is being prepared. Some cases clear up so rapidly that it makes it look like a case of mistaken diagnosis.

The treatment was tried out in about a dozen cases of severe "colds," acute bronchitis, etc., once upon myself. These cases are due to a mixed infection, with the mocrococcus catarrhalis predominating, though the streptococcus is very evident at times. The results were very satisfactory, rapidly diminishing the cough, malaise, and fever, if present, and soon controlling the infection, saving time and much discomfort.

Empyema, 5 cases; pneumonococcus 2, colon bacillus 1, mixed staphylococcus and streptococcus 2. One died of exhaustion, one is still under treatment and nearly well, the others recovered. Empyema of recent origin is undoubtedly benefited by the treatment; but chronic empyema, of long standing, with retracted lung, etc., cannot be benefited much, except to diminish the discharge and indirectly benefit the patient by lessening the toxemia.

Osteomyelitis, 5 cases. Two died of septicemia, 2 still under observation. These are not cases in which the treatment can be expected to accomplish much, as there is generally dead bone present acting as a foreign body, and septic absorption is too rapid. In infected compound fractures, however, the treatment is of undoubted benefit to prevent spread of the infection, as shown by four cases in the present series.

Otitis media, acute cases 17, chronic 6; staphylococcus 5, streptococcus 2, the others mixed infections of staphylococcus, streptococcus, pneumococcus, etc. Many of these cases have been lost sight of after they left the hospital, so that the subsequent course is unknown. In acute cases the treatment seemed of benefit in every instance except one, which went from bad to worse in spite of everything done and had to have very severe operative interference to control it. The treatment generally rapidly lessens the discharge, diminishes the fever, lessens the duration of the disease and the danger of complications. In chronic cases there is very often dead bone present, and the treatment can do little except to diminish the discharge and possibly prevent the spread of the infection to other parts, though recently the writer has had very brilliant results in clearing up an old discharge in two cases, one of four, the other of eleven years' duration. The treatment undoubtedly makes the patients feel better, and they pick up in their general health. Some writers claim that even in chronic cases, if continued long enough, it will assist nature in throwing off the dead bone and curing the disease, producing an ultimate result better than operative interference, as hearing will be less interfered with. The treatment is certainly worth a trial in all cases of otitis media. Theoretically they should be perfect cases for the treatment. Early paracentesis and vaccine treatment will save many a mastoid.

Mastoids, 3 cases, the treatment being given after the radical operation. One died six weeks later of exhaustion (a baby), the other two recovered, one at least apparently being greatly benefited by the treatment.

Pyelitis, 16 cases, all colon infections. These are difficult cases to treat by any method of treatment. An autogenous vaccine can control the infection of the mucous membrane, diminish the pus in the urine, relieve the patient of the toxemia, and give him a subjective cure; but it is very difficult to get rid entirely of the bacteria in the urine, as they are beyond the reach of the phagocytes. These must be gotten rid of by the administration of urinary antiseptics over a long period of time. Such cases, in hospital practice, are difficult to keep track of; but as far as known all were greatly benefited, cured, or are still under treatment. The same observation holds with cases of cystitis; the treatment benefits the patient but it is practically impossible to rid the urine of bacteria by this means alone.

The treatment was tried out in three cases of asthma. One was not benefited at all, a bad case of spasmodic asthma; another is said to be cured, though it is too early to judge; the other is still under treatment and practically cured, according to last report.

The writer does not wish to appear to claim that vaccine treatment is a cure all. It has its limitations, of course. But even if there are cases where it is of no benefit, the case not being suitable for the treatment or the patient not having sufficient vitality to react, still, given with proper precautions, there seems no reason to fear any harm from the treatment. In a personal administration of over a thousand doses of autogenous vaccines, the writer cannot recall a single instance where any evident harm resulted. There were no cases of hypersusceptibility or anaphylaxis, and no evidence of bad effects due to the so-called negative phase. The treatment cannot take the place of surgery, but in many instances it is a very useful adjunct to surgical procedures. It does not interfere with old established methods of treatment, as they can be carried out in conjunction with the treatment, if thought advisable. It is simply a great addition to our armamentarium in the treatment of bacterial infections.

INSTITUTIONAL TREATMENT OF ARTHRITIS DEFORMANS.

By SAMUEL W. BOORSTEIN, M.D.,

NEW YORK.

ORTHOPEDIC ASSISTANT IN MONTEFIORE HOME, CLINICAL ASSISTANT IN THE ORTHOPEDIC DEPARTMENT OF VANDERBILT CLINIC AND THE HOSPITAL FOR DEFORMITIES AND JOINT DISEASES.

As a sequel to the publication of my article "Abstract of Treatment of Arthritis Deformans in the Montefiore Home" in the MEDICAL RECORD of February 10, 1912, I am now giving a more detailed description of the treatment of arthritis deformans. This will enable the interested reader to follow more closely the various steps in the treatment and will permit him to form his own opinion as to the efficiency of these modes of treatment. Many of these treatments can be carried on outside of an institution. This article may, therefore, be of benefit to those physicians who are practising in a locality where no institution of the kind is accessible.

This disease which disables many individuals and throws them as a burden upon their relatives and the community has always been considered incurable. A person who has unfortunately been afflicted with this disease knows that his fate is to remain a live cripple. After taking various treatments at bathing resorts, finally unimproved, he lands in a home for incurables. Not only by the laity has this disease been considered incurable, but also by the medical profession in general. When the final diagnosis was established, the practitioner would say: "I can do absolutely nothing for the patient. Send him to an institution." The homes which received such patients knew that it meant inmates for the remainder of their days. These institutions provided beds for the unfortunates, where they were permitted to remain and slowly deteriorate.

Even the orthopedists to whom these cases were referred have been rather skeptical about any improvement. Fortunately during the last few years a great deal of work has been done in England on arthritis deformans and very good results have been obtained. Great emphasis is put on "systematic treatment." These patients who have been crippled for many years cannot expect to be cured quickly. The physician and the patient must have a great deal of patience and good results will follow.

As mentioned in a previous article, various systematic treatments were undertaken at the Montefiore Home, the Hospital for Chronic Invalids, where patients are admitted for longer periods. After a good deal of patient work, marked improvement in many cases have been reported.

General Considerations.—It has been shown that arthritis deformans is not the name of a disease but is a class name of these clinical groups which include cases of deformities of joints, the specific cause of which is unknown. The changes are due to infection of some unobserved tract. A great deal can be traced to toxemia of the intestinal tract. The gouty type of chronic arthritis, which is one

of purely chemical changes, is not included in this class. Before undertaking the treatment the source of infection should be carefully looked for. The mouth, ear, nose and throat should be examined thoroughly, for these usually neglected localities are the chief places through which infection may enter the system. This disturbing source should be removed at first. If the tonsils are enlarged they should be excised. A very careful examination should then be made of the digestive system for ptosis, delayed absorption, or dilatation of the stomach, and these faulty positions should be corrected. The digestive power should then be tested. Most of these patients suffer with constipation and their urine is loaded with indican and etheral sulphates. It has been observed that whenever patients are suffering with constipation, pain and discomfort in the affected joints are the marked distressing symptoms or, as Sutter expresses it, "Exacerbation of joint symptoms follows digestive or gastrointestinal disturbances." The urine should frequently be examined, and when indican is present in large quantities a high ichthyol or castor oil enema should be given. This procedure greatly relieves the pain. Even two or three enemas a week can be given and thus eliminate distressing symptoms. After a while the condition improves and no more enemas will be needed. Some use purgatives for a short time, but it is better to attempt to regulate the evacuation of the bowels by means of diet or vibrations over the abdomen. Some use saline colonic irrigations. These remove irritating particles in the state of decomposition and at the same time give daily evacuations (Sutter).

Another source of infection is the genitourinary tract; hence the prostate, and in woman the pelvic organs should be examined.

The treatment should be divided into (1) that of the general condition, and (2) that of the joints.

General Treatment.—(a) Hygiene—Outdoor life is very important. Patients may be rolled out every day on wheel chairs, even in the coolest day as long as the weather is dry. Mental, emotional, and sexual rest should be obtained. Grief, fear, and severe nervous shocks have been shown to exacerbate the symptoms. An institution under the direction of a competent physician is the best place for such patients, where they can obtain complete mental rest and follow the systematic treatment without any disturbance.

(b) Diet.—The patient is allowed to eat whatever agrees best with him and an increase in weight is thus encouraged. There is a common belief that it is harmful for these patients to gain in weight. But according to careful observations, since the patients are anemic, there is no reason why the nutrition should not be increased. The muscles are greatly atrophied and it is, therefore, worth while increasing the nutrition. The physiological resistance of the various tissues and the efficiency of the vital activities in general will be augmented. "All that is required is a nutritious mixed diet as generous as can be digested and assimilated by the individual patient without producing putrefaction. It is advisable not to allow excessive meat, but complete deprivation of meat in persons who have long been accustomed to its use in large quantities is followed by loss of strength. In the light of Chittenden's well-known researches it ought to be possible to maintain patients on a relatively low quota of protein as long as other nutrients are supplied in reasonable amounts. Fifty grams of meat daily is enough for an ordinary person." (Sutter.) Sour milk, buttermilk, and kumyss give promise of being helpful in this connection. Some patients who have been kept for a long time on buttermilk diet have shown lack of appetite though their indican has disappeared. Hence it is advisable to give them a more variable diet. It is claimed that the calcium which is abundant in the buttermilk has a beneficial effect upon the bones. It has been shown by Goldthwait, Osgood, and Painter that the bones contain sixty times as much calcium oxide as magnesium oxide, and in these affecions of bone changes marked variations in the calcium metabolism was found. Therefore, some observers were anxious to introduce calcium into the system. But with the use of the calcimeter this fact can be utilized more intelligently. The blood should be examined with a calcimeter or where possible a careful metabolic study of the calcium should be made, and this element should be administered only when a deficiency is found. Calcium can be given in the form of buttermilk or calcium lactate, gram 1, t.i.d.

Some claim that carbohydrates should be reduced. On careful studies it has been found that the carbohydrate tolerance was pretty good in most of the patients and there is no use of reducing it unless the digestive system is disturbed. The use of raw apples, uncooked celery, spinach, and salads is detrimental only for purely mechanical reasons, but these substances have the benefit of helping peristalsis. Sutter claims that irritants such as pepper, mustard, salt, and vinegar should be excluded from the diet. But there is no reason for doing so.

A little alcohol before meals will do no harm to the patients.

(c) Climate.—Dry, uniform climate is beneficial.

(d) In the occupation, continued moistening of hands should be avoided, but ordinary housework is not harmful.

(e) Hydrotherapy.—Bathing is very useful. It increases the sources of eliminating toxins. Patients receive hot-air baths three times a week where they are kept in a closed box for ten minutes at a temperature of 200°–225° F. while the head is exposed and cold compresses are applied. This is followed by a douche of temperature 90° F., force 20 pounds. There is no benefit derived from keeping the patient too long in a water bath. This hot-air bath is of course more effective than the Turkish bath. In the former the patient does not inhale the hot air, since the head is protruding outside the box. The hot air causes perspiration, and thus eliminates a great deal of toxins. The douche acts as a general tonic. The spinal douche is especially advantageous in arthritis deformans of the spine where local treatment cannot be used extensively. Two of our patients have improved immensely as a result of this particular treatment.

Treatment of the Joints.—(a) Dry Hot Air—Baking is found to be very beneficial. Its effects are: (1) It provides an immediate and powerful stimulation of the vital physical parts, and (2) brings an increase of blood to the joint. If this is followed by massage the effect is doubled. An electrical hot-air apparatus especially constructed for each part of the body is best suited for this purpose. In this the joint well wrapped is kept for forty-five minutes at a temperature of 250°-

300° F. Other dry hot-air apparatus can be used with benefit.

(b) Hyperemia, both active and passive, produces good results. The action of the venous or passive congestion is, according to Bier, as follows: (1) It exercises an absorptive effect on the effused products of disease and on new formations that check joint motion; (2) It relieves pain and lessens the activity of progressive joint disease. Passive or venous congestion is attained by constricting the limb with several circular turns of a soft rubber bandage above the affected joints sufficiently to interfere with the return of venous blood but not with the arterial supply. When this is properly applied the joint becomes swollen and dark red in color. The local temperature is raised. This is what Bier calls "hot congestion," as distinct from edema—"cold congestion," that would result if the rubber bandage were applied too tight as to constrict the arteries (Whitman). The rubber bandages are applied for two or three hours daily, slowly increasing the time to nine hours. Finally, in addition the rubber bandages are left on for the entire night. Care should be taken to vary slightly the location of the rubber bandage near the joint for the protection of the skin. When Bier's passive hyperemia is applied before the massage it reduces the pain arising from the massage. Some use active hyperemia by emptying the blood from the limb by raising it, then applying a bandage at proximal end to stop the circulation, leaving it for one minute, then release it, thus producing hyperemia. This procedure is done once a day.

(c) Electricity.—The faradic or galvanic current seems not to produce any beneficial results on the joints. Perhaps some benefit is derived for the atrophied muscles. Static electricity, mainly the wave applied for fifteen or twenty minutes daily, may be used. Sparks may be applied over the spine and general muscular areas for their general effect but not in the acute stage. During the acute stage the static wave current may be applied. The effects of static electricity are muscular contraction, relaxation of muscular spasm, nerve stimulation or sedation, and similar effects upon glandular and circulatory functions and upon the intimate tissue processes. Glandular secretions are increased (Tousey). Some claim to have obtained good results from the high frequency current by applying it two or three times a week, using the spiral wire cage of d'Arsonval or the autocondensation couch (Snow). It has a tonic and sedative influence upon metabolism and the nervous system. Geyser claims that the high frequency current, when applied for thirty minutes to the joint, has a marked effect in stopping the pain.

(d) Massage.—This is the most useful item in treating this disease. It has been shown that the deformities of arthritis deformans are more marked in "well-to-do" people because these can afford to remain in bed and be supplied with all necessities by their servants. The result is that they become bedridden very early. The joints gradually become deformed and flexion is prevailing. The poor patients, on the contrary, have some employment as housework or finding means of subsistence and therefore are in constant motion and thus prevent deformities. The slight trauma produced by the constant maneuvering is not enough to forbid the continuance of daily work. Some physicians advise rest in bed, but according to the opinion of McCrae, Painter, and Goldthwait, only during the acute attack when the redness and inflammation are present, patients may be permitted to remain in bed. As soon as these have subsided, massage and exercise should be begun. We have had several cases in the hospital who were walking patients before an accidental intercurring disease which compelled them to remain in bed for a while, the result of which was that after recovery they could no longer walk around and had to remain bedridden. The deformities meanwhile kept on increasing. Patients usually object to the massage and exercises, as they cause pain, but if the confidence of the patient is obtained, there will be no difficulty in carrying out this part of the treatment.

Massage should not be given too vigorously, and two or three times a week is usually sufficient, and then only to the muscles and not much to the joint itself. While massaging, gentle kneading and circular movements over the joints should be given and more vigorous motions for the muscles above and below. The massage should be administered after some hyperemic measure. In institutions it is customary to give it after the application of hot-water bags, baking, Bier's passive hyperemia, hot-air boxes, or light baths. Patients can do a certain amount of massaging themselves, viz., kneading the hands, knees, and other available joints. This has a double value, for the fingers are exercised while the joint is massaged.

(e) Exercises must be insisted upon and should be begun as soon as the signs of acute inflammation have subsided. Active and passive movements are of great advantage. It is quite hard to induce the patient to do the exercises which really cause pain, but the physician must use his utmost influence to persuade his patients to continue it regularly. Most of them are neurotic, and with these such advice is easier given than followed. With older patients, especially women, this persuasion is more difficult.

The benefit of the exercise can be summed up as follows: (1) It increases the nutrition of the joint; (2) It diminishes the risk of ankylosis and muscular atrophy; (3) It lessens the tendency to contractures. The best proof of the benefit of exercises is shown in the temporomaxillary joint: this, according to McCrae, is often affected, but no ankylosis results because of the constant use of this joint while eating and talking. We had one patient, aged fourteen, who was afflicted with this disease for the last seven years. She was by nature too quiet and spoke very little. As a result, her mandibular joints were affected. She was made to talk and engage in conversation with the other children. The result of this peculiar treatment was successful.

For carrying out the exercises systematically, Zander's or other scientifically constructed apparatuses are the most proper for this purpose. But in the absence of these, one must use his own judgment and properly arrange ordinary exercisers used in gymnasiums. For the hips pulleys attached to the ceiling, the joints being stretched by halters pulled by the patient himself may be used. For passive exercises of the hip, the rocking chair is of advantage. The fingers are exercised by pressing a rubber ball purposely punctured in order to allow a better grasp. The patient should be urged to walk as early as possible.

(f) Prevention of Deformities.—This should be the main aim of the physician. In order to obtain this, exercises are the best means. Great effort

should be taken to prevent contractures, mainly in the elbows and knees. If there is a tendency to great contractures, it is advisable to put the limb in a splint for part of the day or use a light extension for some hours each day. The contracted limbs may therefore be stretched or extended by means of pulleys for two to three hours daily, whereas at night plaster splints may be applied. Of course the reason for applying the latter is to prevent involuntary contractures of muscles during sleep. But care should be taken not to leave the joints in plaster for several consecutive weeks without allowing exercises, since ankylosis is the result.

(g) Treatment of Deformities When Present.—The use of exercises on the various machines will greatly correct some of the deformities. Careful and forcible straightening of the joints will be of great value. We have been successful in straightening some fingers that had been in a contracted position for many years.

(h) Operative.—Much discussion is going on among the various observers concerning this method. Hoffa, Painter, and others are opposed to forcible breaking down of the adhesions, claiming that ankylosis will return and it may result in a worse condition than previous to the operation. The reason for their objection is that the histological phenomena presented by the joint changes in arthritis deformans are those of degeneration rather than of inflammation. This is to say that the reparative and absorptive powers of the joint structures are greatly impaired in this disease. So that traumatism not being susceptible of normal repair might, through the irritation, result in the formation of more fibrous tissue and ultimately denser adhesions. McCrae, on the other hand, thinks that brisement forcé under anesthesia is advantageous, but the joint must not be left immobile. Passive motion should be begun within twenty-four hours. Shortening of the hamstrings may require a tenotomy, but it is advisable not to leave the joint in plaster for a long time. Occasionally arthrotomy may be necessary to rid the interior of the joint of villous thickening. Some advocate the injection of oil into the cavity of the knee to aid increase of movement. Some advise excision of a joint, and Albee has advised an operation for arthritis deformans of the hip. We have many times broken up joints by means of brisement forcé and so far had no bad results.

Medicinal Treatment.—Antirheumatics should be avoided, as these harm a great deal by upsetting the digestive system and increase the joint symptoms. Herter claims that aspirin and salol act favorably, for they are intestinal antiseptics. Tincture of gelsemium is also useful to alleviate the pain, but the pain can be arrested by the above-mentioned measures without any medication. Some have claimed good results from thyroid extract (Skinner). We have tried it for a long time, using the extract from a reliable source and obtained very little beneficial result. It is good for cases where an atrophy of the organ is present and the patient presents definite symptoms of the thyroid disturbance. Thymus, which is advocated by Nathan (0.3 gram t.i.d.) may be useful. We have not used it. Guaiacol carbonate, in increasing doses beginning with 0.2 gram, together with syrup of iodide of iron, 2 c.c., is claimed by Baumatyne to bring good results.

Radium Emanations.—We have given as high as 20,000 units for six or seven months. The solution was freshly prepared before using, but no benefit has been derived from it. Those patients who had gouty tendencies had their pains slightly relieved. The enlarged glands and tophi were diminished. This was reported by S. Wachsmann at a meeting of the Medical Association of Greater City of New York in April, 1910.

For local application on the knees or other joints where the pain is severe and the skin is tender, any ointment answers the purpose; ichthyol (25 per cent.) seems to be the best. An ointment containing chloral hydrate, gram 20; camphor, gram 20; strammonium in lanolin base, gram 60, is also used occasionally. Vaccine treatment is still in the experimental stage.

Résumé.—Each patient as soon as he enters the Orthopedic Department has his casts, *x*-ray of the joints, and photograph taken, and a careful description is made of the joints so that a good record of the changes can be kept. Then a careful examination for place of entrance of infection is made. The digestive tract is examined by means of stomach and duodenal tubes, and radiograms of the tract, after a bismuth test, are taken. The place of infection is treated if possible. Any disturbance of the intestinal tract is corrected. Then, if acute symptoms are still present, the patient is allowed to be at rest for two or three weeks, during which time his joints are kept warm and local applications applied. The diet is very carefully regulated and enemata or colonic irrigations are given twice or three times a week. After that time the following treatment is administered: Baking followed by massage three times a week, "steam boxes" on the intervening days, light baths twice a week, Bier's passive hyperemia for six to twelve hours daily besides being left on for all night, enemata twice a week, static electricity three times a week, exercises daily.

If patients are not in the acute stage the place of infection is cleared up if possible, then the regular treatment is begun, the diet being regulated at the same time.

I am greatly indebted to Dr. George R. Elliott, under whose direction most of these observations were made, and to Dr. S. Wachsmann, the Medical Director of the Montefiore Home, for his kind assistance in this work.

KERATITIS NEUROPARALYTICA AFTER REMOVAL OF THE GASSERIAN GANGLION.

By WALTER BAER WEIDLER, M.D.,

NEW YORK.

Trifacial neuralgia is a painful affection of the fifth or trigeminal nerve, generally due to some form of toxemia or traumatism. The exact lesion is a neuritis or degeneration, usually ascending, affecting any part of the nerve or its nucleus. Bernhardt says that in 66 per cent. of the cases of trifacial neuralgia, it is the first trunk or the ophthalmic division that is involved, but in a small number of the cases the whole distribution of the trigeminus may be affected. Keratitis neuroparalytica is a very serious condition affecting the cornea, often seen after gasserectomy. The operation of gasserectomy is performed for the relief of the condition spoken of as trifacial neuralgia or *tic douloureux*. Most serious complications involving the eyes often follow this operation, and it is with these affections that my paper has to deal, but more especially the neuroparalytic keratitis. Keratitis neuroparalytica following this operation is far more frequent than we are led to suppose from a study of the literature. A great number of these patients develop this affection months and even years after the Gasserian ganglion has been removed. One of the cases reported in this paper is an example of the keratitis coming on a year after the operation. If it were possible for us to keep accurate records of these patients for five years after the ganglion has been removed, I am sure that there would be a much greater number of such cases recorded, and that the percentage of serious eye complications after the removal of the ganglion would be much higher than our present statistics show. It is with this thought in mind that I raise the questions: Is not his loss of eyes unnecessary? Secondly, is it not possible to give the same relief to these patients without the great danger to life by some other form of treatment than the surgical? The medical treatment of trifacial neuralgia has been and is still very unsatisfactory, unless the neuralgia is migranous in origin. Dana has tried the injection of strychnine in 15 cases and concludes that in those cases of facial neuralgia, extending over a period of one or two years, the treatment will invariably arrest or control the disease. In cases that have lasted over six years, and in those cases with neuritis and sclerosis, the results are doubtful, and there may be failures and remissions. In cases extending over 15 or 20 years, the treatment is of no avail. It is well to note that there was not a single eye affection in any of his series.

For the past ten years much attention has been paid to the value of the alcohol injection of the trigeminus nerve and its branches. From the various papers that have been written on this method of treatment, one is impressed with the safety and ease with which it can be done. The relief from terrible pain and agony that is afforded these unfortunate patients and the almost complete absence of the eye lesions make it a duty for the ophthalmologist and surgeon to advise this form of treatment in trifacial neuralgia. Patrick (*Journal of the American Medical Association*, 1912), after the treatment of 150 cases by the alcohol injection method, says that it does not cure, but that there is nothing that does cure this condition except a perfectly executed gasserectomy, and unfortunately these are very rare. The alcohol injection is effective immediately and the relief may last from six months to four years and is effective in cases that have had the cutting operation previously. It is not a dangerous procedure, not a single fatality being recorded. He has only seen two eye complications follow this method of treatment and these were paralysis of the sixth nerve, and a simple keratitis. Both conditions cleared up under treatment. It is especially valuable in the very old and feeble who may have other grave diseases. The use of alcohol injections does not in any may make a gasserectomy any more serious or difficult. Blair (*personal communication*) states that he has treated 70 cases with the alcohol injections, and answers the question in this manner: "As to the comparative value of the extirpation of the ganglion and the deep injection of the trunks, I am convinced that the decision is decidedly with the latter. The patient more willingly submits to the injections, and the resulting paresthesias and anesthesias last as a rule less than six months and the patient is disabled but a few days. With the exception of one case there was no corneal disturbance and no eye protector was worn. In the majority of the cases relief from pain lasted from eighteen months to two years. In some of the cases it has been shorter, while in many there has been no return of pain. In one of these latter the injection was made five years before; this patient having been a sufferer for nine years previously. In every instance, so far as I know, the relief has been again obtained by reinjection." His cases were carefully selected and there was no doubt as to the diagnosis. The patients were carefully examined by the oculist, rhinologist, and neurologist, and it was due to this great care in making the diagnosis that he ascribes his good results.

Campbell (*personal communication*) says that he regards deep injection of the first and second branches detrimental to the eye. In one case that had received three deep injections of the second branch the patient had a progressive deterioration of the eye and at present very little vision. He does not state how many cases he has treated by this method. Keller (*New York Medical Journal*, 1911) reports his findings in 48 cases of the alcohol injections after the method of Levy and Boudanin, extending over a period of three years. He concludes that successful injections or series of injections are followed by relief for about the same length of time as that following the first resection of a peripheral nerve. Reinjections give a longer period of relief than repeated resections. There was not a single case recorded in this number where there was a serious eye complication In one case the patient complained that her eye troubled her very much, and in another case a purulent conjunctivitis developed a few days after the injection. Bodine and Keller (*New York Medical Journal*, 1909), report twenty cases and state that "after a study of our own cases, few in number though they are, together with the cases reported by Kiliani, Hecht, and Patrick, we believe the accumulated experience justifies a favorable verdict in behalf of

the deep injection as a successful palliative treatment in *tic douloureux;* and we believe after careful study of the interesting figures of Schloesser's, together with those submitted by Ostwalt, Levy and Boudanin, that we are entitled to agree with the summary of Hecht: (1) With the pathology of trifacial neuralgia still undetermined and the operation of gasserectomy expedient only in desperate cases and as a last resort, interest in the intraneural injection of alcohol is justified. (2) Alcohol in dilutions of 70, 80, and 90 per cent. appears in clinical trials to be the best remedy in all cases with painful paroxysms of *tic douloureux.* (3) The prognosis of cure in a permanent sense from a single injection is not good. Prognosis in the sense of complete palliation after one or several injections is excellent. Recurrences, however, are to be be expected anywhere from six months to a year." Kiliani (*New York Medical Journal,* 1908), reported 55 cases treated by the Schlosser method of injection and states that it was successful in 52 cases, and further says that he considers it the most efficient form of treatment because it permits of repetition when recurrence appears. In the hand of experienced operators alcohol injection is a comparatively simple operation and practically free from risk.

The surgical treatment of this condition is not to be regarded as a cure, because in many of the cases where gasserectomy has been most successfully performed the pain has returned. What concerns us more is the danger to the eye; and in many cases where gasserectomy has been done keratitis neuroparalytica occurs with the subsequent loss of vision and the eye. This most unfortunate accident happens too frequently, therefore we should consider well before we advise this form of treatment for the relief of this most dreadful disease. Cushing (*Journal American Medical Association,* 1905) reports a series of cases and reviews very thoroughly the grave dangers to the eye after gasserectomy. "Of importance above all others are the postoperative ocular complications, which, since the first attempts to remove the ganglion, have been a great cause of concern to the surgeon. It has been shown, alas, too frequently, that from one cause or another an enucleation of the eye may eventually be necessary, and it is wise to have an understanding with the patient and friends that relief from pain may demand such a sacrifice. Twice in his series of twenty cases this was necessary, and there were a number of serious forms of keratitis and paralysis of different ocular muscles, external and internal. He claims that neuroparalytic keratitis, as a result of the ganglion extirpation, need never occasion anxiety if proper precautions are taken to guard the eye, particularly for a few weeks following the operation. He believes with Hanau, who made a series of experiments in 1896, that all changes of the cornea after trigeminus paralysis are only a consequence of external influence on the eye, unprotected through its loss of sensibility, and that this applies as much to the slight initial lesion, an especial consequence of dryness, as to the extreme degree of keratitis. In regard to the cessation of secretion of the lacrymal gland there is also added danger, but Cushing thinks that the glandular activity returns after two or three weeks, and this may be explained by the gland being activated by fibers from the facial nerve through the great superficial petrosal. The contracted pupil after a few days does not dilate with cocaine, evidencing, according to Schultz, that degeneration of the postganglionic fibers has reached the dilator muscle. With regeneration of these traumatized or divided sympathetic fibers, lacrymal secretion returns, the pupil regains its normal size and the enophthalmos, if it is observed, disappears. The oculomotor palsies have occurred with great frequency when the ganglion is removed *in toto,* but they generally clear up. The commonest sequel is injury to the abducens, and this is explained by the anatomical proximity of this nerve to the upper edge of the ganglion. The pupillary miosis remains for an indefinite period. The pupil reacts to light and accommodation; when eserine is dropped into the eye the pupil contracts; atropine will dilate it. Krause reports that there were no postoperative changes seen in the pupil in any of his cases. Cushing concludes with the statement that from his clinical experience one very naturally inclines to the view that purely traumatic influences or the combination of corneal dryness with infrequent (xerotic theory) or incomplete closure of the lids alone play a part in the causation of corneal inflammation, and that the pure trophic and trophotraumatic and vasomotor palsy theories are hardly tenable for the keratitis neuroparalytica that results in many of these cases as a postoperative sequence. Frazier (*personal communication*) says that from his findings of his series of 50 cases, there were two cases that had serious keratitis following the operation. One of these two cases was Mrs. M. (Case III); the other was a farmer, and I will add a third, Mrs. Y. (Case II). He thinks that keratitis develops more frequently in the removal of the ganglion than after section of the sensory root. He believes that there are trophic centers in the ganglion itself. A great deal depends upon the attention and care given the patient after leaving the hospital. The slightest evidence of trophic disturbances long before there is anything like ulcer formation, should be treated by immediate closure of the lids, and in this precaution we find that Horsley and Keen are in accord. Cushing uses the Buller shield and claims that this is the better method of protection. Frazier thinks that the tendency toward trophic disturbances is very much greater immediately after the operation than at any subsequent time, and if every precaution is taken and the case is kept under continued observation until the critical period is past, corneal disturbance will be a very rare occurrence. Deaver (*Journal American Medical Association,* 1909), in an article on the surgical treatment of trifacial neuralgia by gasserectomy, says that a word must be spoken of the distressing complication which is apt to follow, even when the operation has been well performed and proper care has been exercised by the surgeon, namely panophthalmitis. He recommends the suturing of the lids or the use of Buller's shield as protective measures after all operations for the removal of the ganglion.

The cases of neuroparalytica keratitis after gasserectomy are usually of the most severe form that come to our notice. There is often a gray opacity seen in the center of the cornea, with later a slight depression. The epithelium over this area is exfoliated, and we often have an ulceration following. This loss of epithelium is usually central, but the ulcer may spread to the periphery of the cornea, leaving always a small portion remaining at the corneoscleral margin. The stroma becomes clouded and opaque and later yellowish and this is followed by the formation of a hypopyon. The cornea may

in the graver cases be invaded by the purulent process, so that there may be perforation and prolapse of the iris. In some cases general panophthalmitis is set up with phthisis bulbi, completing the picture. In other cases the process is not so serious and a partially useful eye is retained. The prognosis should be set down as very unfavorable. The course of the disease is rather slow and there is always slight conjunctivitis and ciliary injection. There is little or no pain in the early part of the keratitis, but later when the process extends to the anterior chamber iris, and ciliary body the pain may become quite severe.

The cause of neuroparalytic keratitis has been a subject that has engaged the attention of the ophthalmologist, neurologist, and pathologist for years. It was Magendie who found through his experiments with rabbits that injury to the trigeminus nerve would produce a keratitis and this is the condition which we now call neuro- or trophokeratitis paralytica. As has just been said the neurotropic theory of Magendie is the result of his experiments and he concluded that this was so from the fact that there were trophic fibers running from the Gasserian ganglion to the corneal epithelium through the fifth nerve and ending in filaments of the ciliary nerve. These experiments of Magendie were later confirmed by work done by Bernard and Gaule. It was further shown that when the ganglion was cut or injured neuroparalytic keratitis resulted, but if the fifth nerve alone was cut there was only corneal anesthesia produced. These experiments were supported by the clinical observation of von Greafe, who also attaches great importance to the absence of tears as one of the causes of the keratitis. The trophic and traumatic hypothesis has been held to be the most satisfactory explanation by Parsons, Head, Sterren, and Wilbrand and Sanger. They all admit that there are such trophic nerves in the corneal epithelium and that these nerves play an important part in the protection and safety of the cornea from foreign bodies and accidents. They insist that there must be a central distribution of the nerve roots or ganglion cells to explain the keratitis. The vasomotor theory does not find many supporters. It is claimed by some that after removal of the ganglion there is noted a vasoconstriction of the vessels of the eye, more marked in the pericorneal region (Spalitta). Seydel includes four phenomena in the production of this form of keratitis, namely, vasomotor changes, corneal anesthesia, a paralysis of the sympathetic, and a trauma, all these being necessary for the keratitis and ulceration. Senftleben and Snellen believe that if the eye is properly protected the keratitis would not occur. This we know is not true because we have seen keratitis follow when there was ptosis, and when the eye has been protected by artificial means. The desiccation theory is based upon the claims that the diminution of the secretion of the tears coupled with the less frequent winking of the lids the corneal epithelium becomes dry, and foreign bodies are no longer removed from the cornea, and in consequence necrosis of the corneal epithelium follows, with ulceration. Davis and Hall have made a number of experiments with monkeys, observing the growth of bacteria after injury of the Gasserian ganglion and the trigeminus. They found that they were able to demonstrate the presence of a certain bacillus which they have called *X*. This bacillus was found in 30 per cent. of normal eyes, but was found in all the patients who had neuroparalytic keratitis together with streptococci. In the cases where keratitis did not develop after the removal of the ganglion the bacillus was not found. They therefore conclude that they are justified in suspecting that the presence of the bacillus in the sac is necessary for the production of neurotrophic keratitis.

It will be readily seen from our study of the various causes that have been advanced that all of these different conditions do not exist in all of the cases of keratitis neuroparalytica. Paralysis of the trigeminus or removal of the Gasserian ganglion with trophic disturbances should be regarded as the cause and the absence of the lacrymal secretion; the presence of a foreign body, anesthesia of the cornea, and the presence of some bacteria of suppuration should all be considered as contributing causes or factors. It is not necessary for all of these last named to be present to have this form of keratitis develop, but one or more of these factors are usually present in every case of neuroparalytic keratitis.

The two cases that are reported in this paper are examples of this form of keratitis after the removal of the Gasserian ganglion.

Case I.—Mrs. H. M., aged forty-eight, white, history of trifacial neuralgia of the right side of the face for the past five years. Was treated for the "tic" by the injections of alcohol and had gotten relief from the pain for eight months. On May 12 was operated on for this condition and there was removed the Gasserian ganglion. Three days after the operation patient found that she was unable to open the right eye. The ptosis gradually improved, however, and when I saw her October 10, 1909, the condition of the eye was as follows: partial ptosis, some injection of the bulbar and tarsal conjunctiva the cornea was anesthetic but clear and smooth. In about ten days the cornea showed the presence of a small central ulcer and this condition increased. The eye felt dry and the patient said that when she cried she found that there were no tears in the right eye. *Treatment*—Boric wash, atropine, hot compresses, protargol ointment, and a compress bandage. Arsenous acid was given internally. A very unusual complication was noted at this time. The patient had been out in the cold and on coming into the house she sat close to the stove to warm herself, holding her head near to the stove to warm her face, which was colder than the rest of her body. A few days later she noticed a sore spot over the forehead above the right eye. This became a most distressing neurotrophic ulceration of the scalp. There was loss of sensation for touch and pain over most of the right side of the face, but the sensation for heat and cold was intact. March 30, 1910, the lids were swollen and the ptosis was about the same as when first seen. Profuse mucopurulent discharge and marked injection of the conjunctiva and the ulceration of the cornea involved one-half of its diameter. The ulcer was deep, extending into the stroma and a large hypopyon was seen in the anterior chamber. Iritis and cyclitis with the pupil partially dilated and filled with exudate. Vision was reduced to counting of fingers at one foot and tension was minus one. On October 6, 1910, the skin over the right side of the face was more sensitive to pain and touch. The acute inflammatory symptoms have all subsided, the ptosis remains, and there is also a large leucomatous opacity involving one-third of the center of the cornea. The eye seems to be shrinking and

the iris is atrophic and the pupil shows remains of the exudate. Light perception and projection good. Wassermann was negative as was also the urine. Dr. Frazier tells me that this was the first time that he had seen this complication after the removal of the Gasserian ganglion. In his letter he describes the operation briefly as follows: "The injury to the nerves adjacent to the ganglion was the result of an accident which was quite unlooked for. Just as I was about to pick up the sensory nerves with a special hook which I use for this purpose, the patient's head moved and the hook became entangled in the nerves, which have since been affected. In extracting the hook I exercised the greatest care and thought I had been successful in avoiding any injury to the nerves. The ptosis and the ocular symptoms which developed shortly after the operation I had hoped would be of only a transitory nature." The last time that I saw this patient was on March 26, 1912, and at that time the ptosis was slightly improved. She told me that she massaged her face and eyelids every day and this may account for some of the improvements noted. The superficial vessels of the lids were distinctly engorged and dilated. There is still the complete absence of tears and the corneal epithelium is dry. The lower half of the cornea is opaque from the infiltration and leucoma formation which is penetrated by several blood vessels. There is always some slight injection of the conjunctival vessels above and below the corneacleral margin. In the center of the pupil, which is small, there is a white opacity which appears to be an anterior capsular cataract following the inflammation. Tension is normal, iris reacts to light in the upper half, and the vision is fingers at four feet. Patient complains most bitterly of the sensation of pain and heaviness over the upper part of the face and temple. The eye is painful at times and there are frequent recurrences of inflammatory attacks, when the pain is quite severe. The pain over the lower half of the face has been almost entirely relieved by the gasserectomy, but the patient is most decided in her statement against the operation. She regrets extremely that she ever had the operation performed and is very sorry that she was not advised to be satisfied with the relief that she could have had from the alcohol injections.

Case II.—Mrs. M. Y., aged fifty-eight, came to see me on account of severe facial neuralgia, telling me that she had been treated for this condition for over a year without any improvement. No injection of alcohol; only medical treatment. An operation was performed on March 4, 1909, and the Gasserian ganglion was removed. The operation was quite successful as the neuralgia was relieved. There were no changes seen in the eye, but she was advised to wear a shield over the right eye, which she did for several weeks. She reported at my office for about two months, making weekly visits, and during that time there was no irritation of the eye whatsoever. The eye remained quiet for over a year. She was given glasses for constant wear shortly after the operation. August 24, 1910, she came to see me, complaining of some pain and distress in the right eye. This condition had existed for a week, during which time she had no treatment. The lids were swollen, there were rather free discharges and a marked injection of the bulbar and tarsal conjunctiva. There was a central ulceration of the cornea involving about two-thirds of the cornea. The stroma underneath was grayish and there was a small hypopyon forming in the anterior chamber. The iris was discolored and there was partial synechia, as the pupil dilated irregularly under atropine. Vision was reduced to fingers at three feet. Patient complained of considerable pain in the eye and temple. Treatment consisted in the use of boric acid wash, atropine, dionin, and hot compresses. Tonics were given and later a compress bandage. The progress of repair was very slow and the woman was compelled to work for her living and was not willing to wait for months for a cure to be effected, and with the expectation of a useless eye in the end she urged me to operate, and the eye was enucleated after five months of treatment.

Pathological study of the eye revealed the following conditions: Macroscopic section of the eye shows very nicely the area of ulceration of the cornea with attempted repair. The ulcer was about 10 millimeters in diameter and seems to have not only involved the corneal epithelium but Bowman's membrane and the substantia propria. The cornea is hazy throughout and the anterior chamber is of a good depth. No deposits seen in chamber, the iris is grayish in color, showing the presence of the hypopyon and the inflammation that had accompanied the keratitis. The lens is in position, showing some senile changes. There is also some absorption of the chorioidal pigment at several places. Miscroscopical examination showed the corneal epithelial layer normal and intact around the limbus and extending toward the center of the cornea for about one-fourth of the corneal diameter. The rest of the corneal epithelium has been greatly changed by the ulceration, being entirely absent in the center together with Bowman's membrane. The stroma proper in the center is also destroyed and there is an attempt at repair. The outer layer consists of long flat cells, one or two thick and directly underneath these cells is a homogeneous layer, rather dense, staining deeply with eosin. Directly beneath this tissue are more cells that are round and polyhedral in shape. Bowman's membrane is absent over the center. In the lamina propria near the corneascleral margin, limited to the one side, are seen several new blood vessels, besides, the invasion of lepcocytes is here seen. Descemet's membrane and the endothelial layer are undisturbed. The sections that were cut first did not show any of the hypopyon. The iris tissue presents foci of round cell infiltrations and also the loss of the pigment layer around the pupillary edge showing the presence of the synechia. A section at a lower level shows the angle well filled with leucocytes, pus cells, and fibrinoplastic material. The cellular infiltration has extended to the ciliary body but no further into the eye.

This review of the work done by Patrick, Hecht, Kiliani, Bodine, Keller, Blair, and Schlosser with the alcohol injections for the relief of trifacial neuralgia, with the great alleviation of the pain, and the almost uniform freedom from any serious eye complications makes it appear to be the most satisfactory and safest form of treatment. It should always be advised in all cases of "tic douloureaux" not only as the first measure in the treatment, but in nearly all of the cases as the only form of treatment. It should be persisted in even if it does become necessary to give repeated injections, because of the great ease of performing the injections and the comparative freedom from any dangerous complications following and the absence of any mor-

tality in its performance. The consensus of opinion of the following eminent surgeons, Cushing, Deaver, Horsley, Keen, and Frazier is that the removal of the Gasserian ganglion is an extremely dangerous and difficult surgical procedure requiring extraordinary technique and skill. The mortality rate is from 5 per cent. to 50 per cent., depending on the individual surgeon's training and ability in the performance of brain surgery. Destructive neuroparalytic keratitis follows many of these operations with the ultimate loss of the eye. It is quite true that many of these patients who are in the throes of trifacial neuralgia are willing to sacrifice an eye with the hope of relief from pain, but it may be possible that with further perfection of the technique and the additional knowledge that will come from our study of the alcohol injection method we may see the time when the operation for the removal of the Gasserian ganglion will be no longer necessary. Thus a comparative study of the value and merits of the alcohol injection and gasserectomy has shown that the patient is assured of relief from pain for a varying period of time lasting for six months and in many cases for years. Furthermore there have been over three hundred cases of alcohol injections reported in this paper and in only one case was there a serious form of keratitis that followed, whereas in the seventy cases in which gasserectomy had been performed neuroparalytic keratitis followed in a considerable number of the cases and in four cases enucleation was done as a final resort for the relief of the distressing symptoms which were directly caused by the operation.

THE DIAGNOSIS OF GALLSTONES.

By W. D. HAMILTON, M.D.,

COLUMBUS, O.

The bile leaves the liver through the right and left hepatic ducts. Their union forms the common hepatic duct, and the latter continues as one trunk to the duodenum. At the level of the beginning of the cystic duct it receives the name of the common bile duct. Therefore, the biliary mainline is made up of the common and hepatic ducts. It directly conveys the bile from the liver to the gut, the gall-bladder and cystic duct forming a biliary switch, where the conditions for gallstone formation are most favorable. Though in many of the cases no form of etiological bacterial invasion seems to have been shown, a previous history of typhoid has appeared in a considerable number of the cases.

While gallstones generally form in the gall-bladder, they may develop anywhere in the biliary tract. They may originate in the intrahepatic ducts, and stay there for an indefinite time; and they probably form at times in the common and hepatic ducts. Should their presence in the intrahepatic ducts produce irritation, the vitality of the tissues about them may thus be lowered. If through the lymphatics or blood vessels of the part an infective process were to arise, suppuration might be the result.

Stones which have begun in the gall-bladder may increase in size after having secured the shelter of the common duct. The bile ducts have sufficient resiliency to favor, in some degree, the passage of concretions. Under infective influence their walls may soften and stretch. This is especially observable in the common duct when it contains concretions. Under these conditions the size and lumen of the duct may be greatly increased. When incised, the examining finger can often be inserted into the choledochus. In fact, in chronic cases—usually where very large stones have found lodgement—it may even look like intestine. No doubt the stones are often responsible in a measure for the changes described. As is the case in other parts of the body, stricture or obstruction from any source is liable to be followed by dilatation above the seat of it. Likewise, ulceration and suppuration are prone to occur from these foreign bodies therein contained.

Upon dividing at operation the adhesions about the gall-bladder, an old perforation is occasionally shown, or a cholecystenterostomy which nature has made may be displayed. Angular or sharp stones would favor its occurrence. All such operations should be done under inspection, through a free incision. The want of this precaution may result in the sacrifice of a life. An opening may be found between the gall-bladder and duodenum, or between it and the stomach, or the colon. Such openings call, of course, for repair after removing the concretions. Stricture of the cystic duct may call for the removal of the gall-bladder.

Not often will cancer of the organ be seen early enough to make thorough removal practicable. That cancer of the gall-bladder may occur is the natural result in some gallstone cases where their irritative effects have been at work for years. Routine removal of the gall-bladder is objectionable, as the organ may in after years be badly needed. In five-eighths of the cases the common duct passes through the head of the pancreas—in the remainder it traverses a groove on its under surface—thus, swelling of the head of the pancreas, if of sufficient intensity, will choke the choledochus in the cases in which it passes through instead of behind it, causing obstructive jaundice. In chronic interstitial pancreatitis, or in stricture of the common duct, the bile may be unable to get from the liver to the gut, and cholecystenterostomy may be necessary to save life. In a case of this kind, with a pervious cystic duct, even the proximal portion of the gall-bladder, if left, may be invaluable in an operation for short-circuiting the bile from the liver to the gut. Unless leaving the gall-bladder will make the patient liable to sepsis, colics, or cancer, or unless it has become gangrenous or irreparably perforated, or has been converted into a useless cicatricial mass, a good deal of conservatism may be justifiable before removing it.

The ordinary landmarks within which deep palpation is practised in search for gallstone disease are described by an irregular triangle. Its angles are formed by the ninth right costal cartilage, the ensiform process of the sternum and the umbilicus. If the liver were from any cause greatly enlarged, or if it were from hepatoptosis actually located at a much lower level than normal, the triangle sketched would not be of much use. The gall-bladder will be more liable to be palpable, if it be either enlarged from obstruction at or in the cystic duct, or if its walls be thickened, or if it be packed with stones. It is, however, the presence of tenderness on deep pressure that will tend to rivet one's attention to the gallstone idea, especially if a tumor be even vaguely felt in the gall-bladder region. In looking for such, one will naturally first employ pressure—after deep expiration—close to the right costal margin, and then along the lower and outer side of the triangle. In common duct gallstone cases, or in enlargement of the pancreas, especially

the head of the organ, palpation may be more apt to elicit deep-seated tenderness along the lower fourth of the inner, or median, limb of the triangle above described, or just at the outer side of it, but still within its limits.

The passage of gallstones through the cystic duct is more painful than through the common duct. The pain of such an attack ordinarily originates near the right costal margin. In its implications and behavior it is usually a right-sided affair. It may, however, be referred to the pit of the stomach, or to the right subscapular region. Where it is referred to the left side, it may be due to adhesions between the gall-bladder and pylorus.

In appendicitis, the fact that the pain is usually referred first to the navel and later to the right iliac region, with the frequent confirmatory evidence offered by an apparently more or less vague induration at or near McBurney's point or somewhere in that region, is generally sufficient to enable one to differentiate the two conditions. Its occasional unsually high location, even near the gall-bladder or right kidney, may give rise to doubt which only an exploration will disclose. Meanwhile, its possible location in the pelvis, or right loin, may have been excluded by negative preoperative findings in the search for it.

To distinguish gallstones from ulcer—either gastric or duodemal—certain points should be borne in mind. The pain of ulcer, unless perforation has occurred, is less severe than that of biliary colic, and is more responsive to the use of opiates than is that from the attempted passage of gallstones. Hyperchlorhydria may be present in both cholelithiasis and ulcer. This, in fact, tends to suggest certain diagnostic limitations of gastric analyses, which derive their value largely by association with other collected data in the investigation of cases. More relief to the patient can often be given by lavage and starvation, as Ochsner suggests, in biliary colic than from anodynes alone. The pain of ulcer is more liable to bear a kind of periodical or habitual relation to mealtime than is true of cholelithiasis.

Renal colic deserves passing notice. Pain from loin to groin, and to testicle or labium, may invite attention to the frequency and character of the urinary discharges. One does not like to give the patient a Jordan Lloyd jab in the kidney region. Even a light one though may elicit the sharp characteristic, sword-like pain of venal calculus as testified to by the patient perhaps only too frankly. The importance of saving the urine, for a time at least, for inspection in such a case was shown on one occasion in the writer's experience many years ago, when having planned to make a lumbar section, if still called for, the patient was found next day to be greatly improved. He denied having passed a calculus. Fortunately the urine had been saved. Nothing appeared to the sight but purulent urine, but upon carrying a finger through the creamy fluid a calculus was felt. It was seven-eighths of an inch long and looked like a fragment of an old-fashioned slate pencil. The absence of blood, pus, or sand in the urine, or its negative microscopical appearance, may tend to exclude renal or ureteral calculus. The Roentgen rays may here be invaluable—the more the pity that we cannot rely upon skiagraphy in cholelithiasis.

Jaundice has no doubt too often been waited for to clinch the diagnosis of gallstones, but if it be at any time associated with a case in which there are stones in the gall-bladder and cystic duct only, it must arise from an extension of the catarrhal process in those parts, to the common duct, with some inflammatory swelling of the duct, with resultant encroachment upon its lumen. Jaundice may occur in such a case, but to produce it there must be some obstruction on the mainline, whatever its character. Stones in the common duct, thickening of the head of the pancreas, cancer of it or of the common bile duct, stricture of the latter, or cicatrization of a duodemal ulcer so located as to close the orifice of the common bile duct are to be thought of in explaining jaundice.

One must, however, consider with an open mind the subject of gallstones. Jaundice is quite liable to be present—intermittently at least—in common duct cholelithiasis, and may in such cases be deep and persistent for weeks or months. When it is so deep and persistent one should always consider the possibility of cancer or chronic pancreatitis. But the surgery which is especially to be cultivated is that which is so timely as to be used in the absence of jaundice.

There is no latent period of gallstones. The story of an octogenarian at whose autopsy gallstones were found, there having been no evidence at any time of their having done harm, is no longer so credible to surgeons as it used to be. The symptoms are generally there if we are clever enough to find them. Where we have found them at operation, unsuspected by us beforehand, symptoms to account for them have not been hard to dig up.

It is the function of the bile to assist the pancreatic fat-splitting ferment in the digestion of the fats. Would it not seem reasonable, in view of this physiological partnership, if gallstones were to produce digestive disturbances, or at times pain or vague local distress? A great many so-called inveterate dyspeptics will be found at operation to have gallstones, and most of them without jaundice.

Jaundice may at no time have been present in gall-bladder and cystic duct gallstone cases. In fact, it may never have occurred even in a case of common bile duct cholelithiasis, though this seems uncommon. In the following case history we were unable to say beforehand whether we had to do with duodemal ulcer or gallstones. We were inclined to think it ulcer. Note, if you please, the youth of the patient, and the absence of jaundice:

Mrs. F., aged 22, patient of Dr. Willard Rank, Newark, O., had had, 13 years prior to her admission to the hospital, the first attack of what was called "gastric neuralgia." Attacks occurred once a year until the last five years, when they began to be more frequent. In the beginning of the last year they were of daily occurrence, while in the latter six months they recurred on an average of about once in three weeks. She complained of sour stomach, eructations of gas, and cramps radiating from the epigastrium to the right shoulder. She had at no time in her history had jaundice. There was a little tenderness on pressure over the gall-bladder and common duct.

Operation, Oct. 17, 1907. Cholecystotomy, choledochotomy. Removed 20 stones from the ball-bladder; one from the cystic duct; several from the common bile duct, one being lodged in the ampulla of Vater. The patient recovered, and when last heard from was in excellent health.

Intermittent jaundice may occur, and probably will be observable if the biliary mainline be the seat of concretions.

There have been 205 consecutive gallstone operations in the practice of Dr. Charles S. Hamilton and the writer in the period between January 1, 1907, and April 1, 1912; 186 recovered, and 19 died—a general mortality rate of 9.26 per cent. In 43 cases stones were found in the common or hepatic ducts. Of these, 9 died and 34 recovered. Twice the cystic duct was large enough to make it possible to bring the stones back out of the common duct through the cystic duct, making them extricable through the gall-bladder incision. Both patients recovered. In one case only in the entire series, so far as is known, were concretions permitted at operation to remain in the choledochus, and it terminated fatally. The patient had coincident cancer of the pylorus, requiring a rather extensive partial gastrectomy. The gallstones were removed from the gall-bladder and the organ drained, while those in the choledochus were left in situ. Forty patients required calculous choledochotomy; 32 recovered, and 8 died—a 20 per cent. mortality for those cases in which the common bile duct was incised for the removal of concretions therein contained.

Few, if any, of the fatal common bile duct cases were promising operative subjects. Jaundice, with liability—especially if deep—to post-operative hemorrhage, sepsis acute or chronic, with the impaired physical resistance which long suffering had produced, were the more usual impediments to recovery. A few of the common duct cases might have survived provisional drainage of the gall-bladder merely, thus mitigating the "bottled up" biliary sepsis, so that a later choledochotomy might have been successful.

In the diagnosis of common duct cases one often finds the history of ague-like chills, fever and sweats from biliary sepsis. One may find, too, sometimes, deep-seated tenderness one inch to the right of and above the navel. If at operation one finds a shrivelled gall-bladder—cholecystitis obliterans—one naturally assumes that concretions may be found too in the common or hepatic ducts. A large gall-bladder with jaundice may suggest, according to Courvoiseur, Robson, and others, cancer of the pancreas or the bile ducts.

In 26—about 13 per cent. of the 205 cases—enlargement of the pancreas—usually its head—at least was found. A few had acute infections of the pancreas with fat necrosis. The most of them were cases of chronic pancreatitis. Cancer of the pancreas was not often observed.

ABORTION—ITS SOCIAL AND ETHICAL ASPECTS.*

By CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

VISITING PHYSICIAN TO BELLEVUE AND TO ST. VINCENT'S HOSPITALS; PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE AT NEW YORK; PRESIDENT, GUILD OF ST. LUKE.

"Abortion should be undertaken as reluctantly as one would commit justifiable homicide."[1] But inasmuch as homicide is sometimes justifiable, so are there circumstances which not only justify, but imperatively command, the induction of abortion by the conscientious physician. These circumstances are well established and generally easily demonstrable. But their occurrence is rare in comparison with the vast number of cases in which childbearing is deliberately evaded for social, economic, or luxurious reasons, and in this country, as well as in other parts of the world, decreasing fecundity, or decline of the birth rate, is a question which should give statesmen, citizens, the reverend clergy, and legal and medical men grave concern. It is the proud boast of physicians that medical science has made wonderful strides in the last fifty years. The results of this are shown in a marked decrease of the death rate, owing to preventive medicine, improved sanitation, and intelligent quarantine. In this onward march of medicine, obstetric and gynecic science have taken part. Women have been relieved of many of the perils of child birth, congenital errors of development causing barriers to conception have been removed, acquired diseases of women's reproductive organs have been cured, and we have reason to look for a large increase in the birth rate as a consequence. Instead of that, we find that the average number of children to each marriage has declined from 4.5 at the close of the eighteenth century to 2.0 at the end of the nineteenth century.

At the present time the birth rate in this country is lower than that of most European countries, being much like that of France. It is even less than that of France in some States.[2] Yet we are accustomed to think of France as degenerate, and to regard her low birth rate as an index of her morality.[11] To be sure, our death rate is less than the death rate of France, which exceeds that of her birth rate, and this fact alone protects us from the national decay which threatens any country where more people die every day than there are children born.[3] We are not alone in this decline. Most countries where statistics are kept with reasonable accuracy show also a decline of from one to six births per thousand of population since 1875. The brilliant exception to the condition is Japan, which has shown other unmistakable evidences of vigorous growth during the same period.

In this country we complacently rely upon the enormous influx of foreigners to our hospitable shores to maintain and increase the population. And it is well that we can afford to do so, to a certain extent. For it is upon the foreign-born parents that we must rely to maintain our birth rate. The average number of children to a marriage is 2.1 to each American woman and 3.8 to each foreign woman. The higher we go in the social scale, or in the intellectual scale, with American women, the lower do these figures fall, the highest social classes showing 1.8, and married women who are college graduates only 1.3.[5] In intellectual Massachusetts a study of the census shows, among the native population, a special birth rate of only 6.3 births for every 100 adult women of child-bearing age.[4] That of Berlin, a city not noted for its excessive morality, shows, for comparison, a special birth rate of 10. There is, then, the sting of truth in the statement that the descendants of the Pilgrim fathers now inhabit Mount Auburn Cemetery while the sons of Aliens live on Commonwealth avenue. And this is not alone true of Massachusetts. Even a young, vigorous State like Michigan does not afford enough children per marriage to keep itself intact.[6] To bring the matter nearer home, the statistics for our own city of New York, for the past year, show the average number of births per 1,000 of the population to be distributed as follows, among the American-born

*Read before the Bronx Medical Association, April 25, 1912.

and foreign-born mothers: Italian mothers, 46; Hebrews, 35; Irish, 25; Americans, 14.[7] The social, economic, and political significance of these figures may well invite the attention of our governing bodies. It will be noticed that the figures for American-born mothers are even lower than they were twenty-five years ago. But *it is not the American wife who reduces fecundity* as much as it is the American husband.[2] This is proved by figures which show that the children of foreign fathers who marry American-born women show a higher numerical average than those resulting from marriages where both parents are American. This race suicide means the decay of spiritual ideas and the death of true patriotism. Every physician knows that the limitation of the number of offspring is mainly volitional. The number of marriages which are unfruitful through no fault of the parents constitute but a very small percentage of the cases of sterility. The causes of this voluntary avoidance of the joys and sorrows of parenthood are many, but as it exists to the greatest extent among the comfortable classes, "the gospel of comfort" is the main factor. Gonorrhea and syphilis undoubtedly play some part in holding down the birth rate, but pale into insignificance beside the number of cases of wilful prevention of conception and interruption of pregnancy. So many women are now employed in various pursuits that marriage, and, after marriage, maternity, is avoided so that the family income may not be diminished. The so-called emancipation of women has led many others to look upon the old-fashioned dignity of motherhood as unbecoming to those who desire the political privileges of men and brothers. The aversion of many wives to normal conjugal relations is driving many husbands to the society of mistresses and harlots. It is well known that these women derive their chief support from married men. The struggle of the early years of professional life induces many physicians, lawyers, and even clergymen, to seek to limit their responsibilities. In a canvass of 64 married physicians, 15 years after graduation, Hunsberger[8] found that only 105 children had been begotten. It is to be hoped that this proportion is not true for all medical graduates. If it is, our profession hardly deserves the title of "guardian of the rights of the unborn child to live." Legislators depend upon us to suggest suitable laws to punish the abortionist. Moralists and theologians rely upon us to furnish the facts to enforce the truth on this subject upon the moral sense of the community. We should come into court with clean hands, and let our light so shine before men that they may see our own good works. If we are to throw the weight of our influence against conjugal onanism we must demonstrate that we ourselves can hand on the torch of life with unimpaired brilliancy. Of course, we must be prepared to meet the argument that "to insist upon the duties of motherhood is an impertinent interference with private rights," or "that there is nothing so wearying to the nerves as the constant care of little children,"[9] but every right has a corresponding duty, and the marital right carries the duty and the glory of parentage, and the mother who has taken to her breast many little children is far less likely to become nerve weary than she who tries to avoid or prevent conception, if possible, or to terminate pregnancy prematurely, if need be. The evil in the latter case is not only individual, it is national. We have only to look at the once powerful magnanimous, chivalrous, pious France, now humiliated, bleeding, and prostrate at the feet of a relentless foe,[10] to realize this, and to condemn the Judases of our own profession who for pieces of silver are willing to dabble their hands in innocent blood. If some of the well-meaning but misguided people who are now so solicitous about enforcing laws for the protection of the guinea pig would direct their time and energy to measures designed to stop the wholesale slaughter of innocent unborn children, future generations would rise up and call them blessed. When the men of Rome offered their highest homage to the mothers of families that nation was at the height of its imperial greatness. But when the Romans transferred their affections and homage to their mistresses, decay was not far off.[8]

The ethical aspects of abortion need not detain us long. There is no ethical question to be solved by the man who believes that there is a God, and that this God gave to Moses on Mount Sinai, the commandment "Thou shalt not kill." To the man who does not so believe, argument is a waste of time.

Serum Therapy of Postdiphtheritic Paralysis.—U. Calcaterra finds that the later a case is injected with antidiphtheric serum the more apt it is to have a sequent paralysis. The intraspinal injection of the serum has no effect in warding off the paralysis or in decreasing the mortality. The serum treatment of the paralysis is not of any value.—*Rivista di Clinica Pediatria.*

Obstipation of Four Months' Duration from Megasigmoid.—Luria reports a case of Hirschsprung's disease in a young woman which differs from the ordinary type of megacolon. The patient before the present attack was used to attacks of fecal retention lasting from a few days to several weeks and terminated by copious spontaneous evacuations. She came under observation on the twentieth day of one of these attacks and the author began to control the case with the *x*-ray and endoscopy as well as by ordinary physical diagnostic procedures. The present attack was associated with pregnancy. Considering her ailment the woman's general condition was surprisingly good. Her appetite was somewhat diminished. Meteorism was not in evidence nor were there any symptoms of autointoxication. The sequence of the history is not given, the author being chiefly concerned with establishing the diagnosis of megasigmoid. His claim that the fecal retention is the longest on record may not take cognizance of extreme cases in hysterical subjects.—*Deutsche medizinische Wochenschrift.*

VACCINATION WITH LIVING SENSITIZED TYPHOID BACILLI IN TYPHOID FEVER.

THE results obtained by Metchnikoff and Besredka in the immunization of the chimpanzee against typhoid infection by means of the inoculation of sensitized living typhoid bacilli suggested that similar results might be obtained in the case of human beings. To W. Broughton-Alcock, working in the laboratory of the Pasteur Institute, was assigned the task of testing the practical value of this method of immunization. His results, published in the *Lancet*, August 24, 1912, supply a new and interesting chapter in the history of immunotherapy.

The method of employing living microorganisms in the inoculation of animals for purposes of immunization was first suggested by Besredka, who thought that the living organisms would give rise to an immunity response similar to that resulting from a true infection, while the phagocytosis and bacteriolysis of the sensitized bacilli would prevent any danger of the inoculated individual becoming a carrier. This method is analogous to that of vaccination for smallpox in which a living virus is also used. The typhoid bacilli are sensitized by the addition of antityphoid horse serum, and remain alive in this condition for four months without exceptional precautions.

The chief advantage claimed for the use of the living bacilli, with which there have already been inoculated 750 persons, including many soldiers, is that there is no general reaction and only an insignificant local reaction following the injection, in marked contrast to the reactions following the injection of an equal number of killed bacilli. As recommended by Besredka the bacilli are injected in two doses, at ten days' interval. The first dose for a woman of average size is 500,000,000 sensitized living typhoid bacilli suspended in 1 c.c. of 0.8 per cent. saline. For a man of good physique the first dose should be 750,000,000 bacilli. The second dose administered from seven to nine days later is twice as large. An elevated temperature, a previous history of typhoid fever, and the time of menstruation do not contraindicate the inoculations.

As regards the ultimate efficacy of this method in preventing typhoid infection there are as yet no data except those obtained by Metchnikoff and Besredka in the case of the chimpanzee. Broughton Alcock states that the sera of the vaccinated individuals have not been found to deviate complement and have been found only rarely to agglutinate an emulsion of a young culture. But the addition of these sera markedly increases phagocytosis, and it is suggested that the former may also contain antiendotoxin bodies. Experiments *in vitro* with reference to the presence of specific amboceptors, agglutinus, and bacteriolysins do not indicate the degree of immunity attained.

On the basis of his interesting results, taken in conjunction with the experimental findings of Besredka and Metchnikoff, Broughton-Alcock concludes that the living sensitized typhoid bacilli are innocuous, and that they ought to be used by preference in the immunization of human beings.

ACROMEGALY FROM THE SUFFERER'S VIEWPOINT.

"WHEN fate, shaping my 'ends,' decreed that I was to suffer from the malady acromegaly, she perhaps gave me the greatest compensation possible by causing me to enter the medical profession. After the distress caused by the one and the enjoyment due to the other—both extending over more than a quarter of a century—I find myself in the unique position of being able to relate a personal experience of this rare complaint as it affected one with some medical knowledge." With these well chosen words Leonard Portal Mark prefaces the extraordinary narrative* that may be termed the autobiography of an acromegalic. The most singular point about this history is the fact that the victim of this disease suffered from its symptoms for thirty years and that for two-thirds of this period whenever he looked into the mirror to brush his hair or to shave, a typical acromegalic was staring him in the face, and yet he never recognized this fact! This is another illustration of the observation that has been frequently made that physicians who are keen in detecting the presence of disease in others are frequently oblivious of its existence when they themselves are the unfortunate subjects. In the case of an incurable malady this ignorance may be a fortunate compensation. The friends of Dr. Mark knew for many years the secret of his changing physiognomy, of his enlarging hands and feet, and of his patient suffering, yet they wisely kept from him the knowledge that would have increased the burden that he was obliged to carry.

The author of this book has made an important contribution to medical science in describing the insidious onset of this disease and its numerous subjective symptoms. The usual conception of acromegaly is that which is derived from a consideration merely of the anatomical changes accompanying it. The subjective symptoms, however, are the more important ones from the victim's viewpoint. The

*"Acromegaly, a Personal Experience," by Leonard Portal Mark, M.D., late President of the West London Medico-Chirurgical Society, and Pathological Draughtsman to St. Bartholomew's Hospital. London: Baillière, Tindall & Cox, 1912.

practice of keeping a diary ever since the age of fourteen enabled the author to fix the earliest manifestations of his affliction. These were present when he was twenty-four years old, in 1879, about seven years before Pierre Marie recognized the disease and gave it a name. The first abnormal sensations were perceived when the sounds from a piano did not seem clear, as if the notes were double, and when at the same time there was a sensation as if the left ear were stuffed up by a foreign body. These sensations were then attributed to a Eustachian catarrh. During the next two or three years there occurred peculiar feelings in the head, and periodical attacks of "malaise," associated with subjective sensations of cold, inability to fix the attention, and giddiness. These sensations were worst in the morning. Seven years after the insidious onset of the disease there developed a persistent left-sided face-ache, which was aggravated by fatigue and by cold. But the most distressing symptom was the headaches to which the sufferer was subject for twenty-four years. During the first six years of this period the headaches were of a neuralgic nature, and were acute, frequent, and of prolonged duration. The terrible aching in the left side of the head was aptly described by the popular expression "a splitting headache," and was apparently caused by a growth within the cranium, slowly pushing its way in different directions. During the second period, from 1893 to the present time, the headaches have been less of the neuralgic type and more akin to fatigue or lassitude. During this time a more predominant feature has been what the author terms the "acromegalic state." This, with the headache and face-ache, constitutes a triad of symptoms. The manifestations of the acromegalic state are a general feeling of discomfort, a sensation akin to that produced by a narcotic, a feeling of restlessness or a desire to keep absolutely quiet, intolerance of noise or light, a feeling of giddiness, dyspnea, and mental depression. At the same time the face is pale, the lower lip is much more prominent and drooping, there is ptosis of the left eyelid, and the hands and feet become larger, and moist and cold. The acromegalic state which seems to be a sign of low vitality or of lowered blood pressure comes on imperceptibly and passes off in the same way.

Although the author had excellent eyesight in early life, he began to experience trouble with his eyes at the age of twenty-four, when he would have photophobia and his lids would become red and swollen. At the age of thirty-eight there was discovered an astigmatism which accounted for the asthenopia. Ten years later the astigmatism disappeared from the right eye, which was explained by the anatomical changes in the bony walls of the orbit causing a change of pressure on the eyeball. Another distressing symptom was the lacrymation attributed to an hypertrophy of the lacrymal glands. Second in importance to the ocular troubles were the nasal symptoms, which consisted of frequent "colds." These were supposed to be due to a postnasal catarrh and hypertrophy of the turbinates. Two marked subjective symptoms of this disease were a pronounced lethargy and the sensation of noises in the head.

In detail the author describes the physical changes of acromegaly, the enlarging hands, feet, and lower jaw; the inconvenience caused by the malocclusion of the teeth, and the enlargement of the tongue. Other troubles noted are the sudden loss of power in the legs, the development of trophic sores on the toes, and the occurrence of cardiac insufficiency as manifested by attacks of dyspnea on exertion and of irregularity in the heart's action.

In discussing the causation of the multitude of symptoms that go to make up the complex clinical picture of acromegaly, Mark notes that many of these have purely a local significance and are connected with the bony changes within or in the walls of the skull. The headaches, the acromegalic state, and the lethargy may be caused by toxins, by variations of blood pressure, or by the presence of a tumor at the base of the brain. The bony and visceral hypertrophy is attributed to a sensitization by some substance emanating from the pituitary gland, or to a disturbance of the interglandular equilibrium. One striking characteristic of the author's case is the difference in character which has marked the earlier and the later symptoms: the earlier symptoms were of a neuralgic while the later symptoms have been of a lethargic nature. Possibly the former were caused by hyperpituitarism and the latter have been caused by hypo- or dyspituitarism. A skiagram of the author's skull shows a pituitary fossa twice the normal size and it is surmised that this contains an abnormally enlarged pituitary gland. It was only seven years ago that the light suddenly dawned upon Dr. Mark that he had acromegaly. Fortunately since this revelation and even in the absence of any special therapy the symptoms have undergone decided improvement. The sufferer finds that there is still much in life that he is able to enjoy, in spite of slight "unsoundness of eyes" and a gradually increasing "weakness of wind and limb."

MECHANISM OF SALVARSAN DEATHS.

It may be taken for granted that severe phenomena following salvarsan injections do not differ among themselves essentially in fatal and recovered cases. An analysis of fatalities alone does not appear to throw much light on the mechanism of death. It is highly probable from analogy that many deaths from this and other powerful drugs are in the full sense of the word accidents due to the fortuitous association of a number of elements, the absence of any one of which might have spared the individual.

A recent analysis of severe and fatal cases by Lesser showed the presence of two groups, in one of which after from three to five days fatal coma sets in, the patient succumbing within twenty-four hours. In the other type the symptoms do not develop for weeks and the patient recovers. Since this analysis was published Hammer has published a fatality corresponding to Type I (*Münchener medizinische Wochenschrift*, July 23), in which, despite the fact that patient was a young vigorous

subject infected within a year, he already presented severe syphilitic alterations of the heart and aorta. Ehrlich from the first warned against these lesions as forming a contraindication to the use of salvarsan; and it is probable that this formed an important link in the chain of causal factors.

In the same number of the same journal Hirsch reports two fatalities which do not belong to Lesser's first group. While the two appeared to show the same syndrome of fever, jaundice, cramps in the calves, convulsions, coma, etc., which pointed strongly to arsenical poisoning, one patient was taken acutely ill after the second injection, the other was not attacked until all treatment had been discontinued and patient was free from symptoms. These cases showed a strong supersensitiveness to arsenic, the first one suggesting a condition analogous to anaphylaxis, while the other patient was suddenly attacked over four months after the injection. As an autopsy could not be obtained in the second case its nature must remain dark.

The number of possible factors in salvarsan poisoning is now very large. Leaving aside such possibilities as an embolism and status lymphaticus which used to be invoked in parallel cases, we have to consider both anaphylaxis and cumulation, and the sudden liberation of endotoxins acting in concert with the drug itself, which combination is believed to be highly deleterious in syphilis of the heart and aorta, meningitis, and other conditions. Impurities in the solution and the reaction of the latter have received much attention in this connection. Comparisons have sometimes been instituted between salvarsan and methyl alcohol as neurotropic substances, and poisoning with the latter appears to be due to the formation of by-products from imperfect attempts at oxidation. It has recently been shown of the action of two synergists that with only a fair dose of one a mere fractional dose of the latter will double the effect. This cooperation might be invoked as a factor in drug poisonings. The number of possible factors in such cases could be considerably amplified.

SERUM IN THE TREATMENT OF SCARLET FEVER.

The manifestations of scarlet fever are due to two causes, the unknown virus of scarlatina itself and the streptococcus that is almost invariably present in addition. Of course, really specific treatment by means of sera or antitoxin is out of the question so long as the cause of the disease is unknown, but enough evidence has been accumulated that the accompanying infection with the streptococcus is frequently the main element which makes scarlet fever such a dreaded disease. It is not surprising, therefore, that antistreptococcic sera should have been advocated in the treatment of the disease, and of them Moser's serum, first prepared in Vienna under the supervision of Paltauf and Escherich, has had most prolonged and carefully observed trial. Moser tried the effect of his serum in 84 cases, with the following results: (1) The earlier the injection the better the result. (2) Large doses are preferable to small ones. (3) Fever is cut short abruptly by the injection, the throat symptoms are made much lighter, the nervous symptoms disappear. (4) Complications (septicemia, nephritis) become infrequent. (5) The mortality is reduced. Numerous Russian authors, in whose land scarlet fever is often a veritable scourge, decimating the children in the villages, have tried Moser's serum and have spoken very favorably of it. Thus Egis and Langovoy have used it in several hundred severe cases and think that the mortality in their cases dropped from the usual 47 to 16 per cent.

In a recent number of the *Wiener klinische Wochenschrift* (Vol. XXV, No. 24) Dr. Oscar Szekeres tells of the favorable impression produced by the use of the serum in Hungary. The injections were followed constantly by a drop in the temperature and a very marked diminution of the symptoms of toxemia. The duration of the exanthem appeared to have been shortened, and complications made rarer. It seemed also that the serum could be used as a prophylactic, exposed children being very rarely attacked by scarlet fever if injected with the serum.

These results are simply confirmatory of those previously published. They, however, serve to call attention once more to Moser's serum and the undoubted good effects produced by it. Its manufacture is not as simple as the production of vaccines, involving as it does the isolation of streptococcus from the blood of patients severely ill or dead of scarlet fever, and the injection of living cultures of these streptococci into horses. This may explain why of late vaccines have been so much exploited in comparison with such sera as Moser's. The latter, however, should find extensive trial, for if it does even a moderate part of the good claimed for it, it forms a valuable weapon in the fight against the mortality of scarlet fever.

BIOLOGICAL SIGNIFICANCE OF THE THYMUS.

Until very recently the thymus has been looked upon as having no necessary significance for the integrity of the individual, but recent studies by Klose and others have demonstrated that the organ is actually indispensable to life. Negative results of earlier years are clearly seen now to have been due to defective technique and defective knowledge of autogeny. The gland must be removed at the height of its activity and with due aseptic and other surgical precautions. When this is done in the newly born dog no changes in growth rate are at first apparent. This is the period of latency, which lasts from two to four weeks. Thereupon there ensues a rapid accumulation of adipose (stadium adipositatis), while the bones and organism at large show progressive enfeeblement. When the animal is three or four months old, the stage of cachexia develops, and is attended eventually with mental failure called thymic idiocy. At the age of 14 months or thereabout, the animal perishes.

Last spring before the Verein der Aerzte of Halle (*Münchener medizinische Wochenschrift*, August 13) Lampé went exhaustively into the spe-

cial features of thymus deprivation. The bone changes are characteristic of the latter. The longitudinal growth is arrested and osteoporosis, rachitis, and osteomalacia appear, due evidently to lack of undissolved calcium. Fractures in such animals cannot heal by callus formation, and fibrous union occurs. Klose believes that thymus extirpation causes acidosis and that the excess of acid in the economy prevents the deposition of the lime salts. The inference is that a natural function of the thymus is the prevention of acidosis. Thus free phosphoric acid is rendered harmless by the nuclein synthesis. The changes in the nervous system are parallel with those of the bones. There is a peculiar swelling and liquefaction of nervous substance, presumably due to the acidosis. This is expressed clinically in many ways. The coma which results in time from this mechanism is readily intelligible. Extirpation of the thymus is followed by diminution of lymphocytes in the blood, which may be made good by thymus grafts or injection of extracts. There is a compensatory hypertrophy of the genital glands after thymectomy, while the thyroid, pancreas, and spleen are similarly affected. Those with persistent thymus usually have very small genital glands. The spleen is probably the organ best suited to compensate for the loss of the thymus.

Neosalvarsan.

Salvarsan was number 606 in the list of arsenic compounds which Ehrlich made in an endeavor to produce a drug which should be non-toxic to man and yet fatal to spirochetes in the body. Its success was marked and immediate, but the chemist was not satisfied and continued his work along the same lines. Number 914, the next to merit attention, he has named neosalvarsan. This drug is a condensation product of salvarsan and sodium formaldehyde-sulphoxylic acid; it contains one-third less the percentage of arsenic so that, theoretically, the dose should be half as much again as that of salvarsan. H. E. Kersten (*Centralbl. f. Bakt.* vol. 65, p. 369) has conducted comparative animal experiments with the two drugs and finds that this is not the case. With the introduction of a new group the toxicity of the arsenic compound has been changed. According to this investigator, the minimum fatal dose of the new drug is, for rabbits at least, over twice that of the original salvarsan. The therapeutic powers were tested upon mice infected with *Spirocheta obermeieri* and *Trypanosoma brucei*, with the result that the dose of neosalvarsan necessary to cause the disappearance of the parasites from the blood was about one-half that of the older drug. If these differences appear also in the effect of these drugs upon man, we must consider the new substance a valuable addition to our chemotherapeutic agents. Still, neosalvarsan is very new and should be used with extreme caution until it may be possible to draw definite conclusions as to its value. Not the least of its advantages is the fact that it is easily soluble in water and that such a solution has a neutral reaction, so that there is no need of the preliminary neutralization of the solution as there is in the administration of salvarsan.

Fighting the British Insurance Act.

Domestic servants, their employers, clerks of both sexes, and others are fighting the British Insurance Act with tooth and nail. A new organization has been formed by the disgruntled ones entitled "The Amend-the-Act League." This league, which is non-political, has adopted as a method for attracting supporters and registering them as members the sale of a penny (two-cent) "amend-the-act stamp." The stamp is large, with an allegorical design printed in brown. Forms are to be sent in with the stamps. Each of the forms has twelve squares upon which the stamps are to be stuck, and there is a place for the name and address of the buyer opposite each square. Every buyer of a stamp becomes a member of the league, and while the money received for the stamps goes to swell the funds of the league, the names and addresses form a register of the members of the organization. The stamp idea is taken, in a spirit of audacity, from Chancellor of the Exchequer Lloyd-George's own scheme, but the officials say with this difference: "It is better to lick a stamp once to help in getting the insurance you want than to lick stamps for years in payment for what you don't want." It is said that the movement is making headway.

News of the Week.

New Plague Cases in Porto Rico.—A despatch to the Public Health Service from Porto Rico last week told of a continuance of bubonic plague in the island. A suspicious case reported from Puerto de Tierra was confirmed and a new case was reported from Santurce. This brings the total number of cases in Porto Rico up to fifty-one. The total deaths have been twenty-seven.

Watching for Cholera Carriers.—Officers in charge of the Public Health Service quarantine stations, which comprise most of the stations in the country, with the unfortunate exception of New York, have been warned to be on the lookout for cholera carriers. Double examinations of all entering aliens will be prescribed until the present outbreak of cholera in southern Sardinia and Italy and in Beirut, Syria, subsides.

Concealing a Diphtheria Epidemic.—A despatch from Toronto last week said that thirty deaths from diphtheria had occurred at St. Vincent's Infant Home in that city during the past few months, although the knowledge of the outbreak has only just been made public. There are about one hundred children in the institution, of whom ten or fifteen are now suffering from the disease. The authorities have treated those not yet attacked with prophylactic injections of antitoxin.

Street Fatalities in New York.—During the month of August this year 18 persons were killed in New York City by automobiles, 17 by horse-drawn vehicles, and 13 by trolley cars, making a total of 48 deaths from street accidents. In the same month last year there were but 24 deaths, 7 from automobiles, 13 from horse-drawn vehicles, and 4 from trolley cars. In the year 1910 there were 376 street killings, in 1911, 423, a number already nearly reached in the eight months of the present year.

Glanders in Philadelphia.—A fatal case of glanders in man has occurred in Philadelphia. The sufferer contracted the disease from a horse that he had purchased a short time previously.

Health Rules on Match Boxes.—It is stated in *The Sun* that the Grand Duchess of Hesse has induced all the manufacturers of matches in the grand duchy to have printed on their paper wrapping boxes the rules for fighting tuberculosis. This idea, which seems to have originated in South America, likely will be extended in Germany.

Pennsylvania State Board of Medical Education and Licensure.—Dr. J. M. Baldy of Philadelphia, president, and Dr. D. P. Maddux, of Chester, have been reappointed by Governor Tener to membership on the Pennsylvania State Board of Medical Education and Licensure, to serve for three years. Dr. Wm. A. Stewart, of Pittsburgh, has been appointed a member for one year, to fill the unexpired term of the late Dr. Seip. The remaining members of the Board are Dr. J. T. Johnsonbaugh, of Bethlehem, whose term will expire September 1, 1913, and Dr. Adolph Koenig, of Pittsburgh, whose term will expire September 1, 1914.

The Vaccine Treatment of Typhoid Fever.—Dr. W. H. Watters, Director of the Department of Pathology and Bacteriology, Evans Institute for Clinical Research, Boston, Mass., requests reports of cases of the vaccine treatment of typhoid fever, to be used in a forthcoming article on this subject. Due credit will be given in the article to each person favoring him with such report.

Reception to Visiting German Physicians.—As previously announced, the German Medical Society will give a reception to the German members of the Congress on Hygiene and Demography, at the Liederkranz building, East 58th street, on the evening of September 18. Physicians, not members of the German Medical Society, who desire to attend this reception, may purchase tickets from Dr. Wolff Freudenthal, 1003 Madison avenue.

Gifts to Charities.—The will of Nathan Herrmann, who died on August 23, disposes of an estate estimated at over $1,000,000 and gives more than $90,000 to forty charitable and religious organizations. Mr. Herrmann left $15,000 to Beth Israel Hospital, $10,000 to the United Hebrew Charities and $5,000 each to the following: Montefiore Home, Mount Sinai Hospital, Hebrew Sheltering Guardian Society and the Hebrew Orphan Asylum. Institutions to receive $2,500 each were the Sanitarium for Hebrew Children, Jewish Protectory, Educational Alliance, Technical School for Hebrew Boys, Technical School for Hebrew Girls and the Hospital for Deformities and Joint Diseases. The will left $1,500 to the Institute for the Improved Instruction of Deaf Mutes and $1,000 each to eighteen other institutions. The Home for Aged and Infirm Hebrews and the Lebanon Hospital also received each $2,000. By the terms of the will of Cyprian S. Brainard, Jr., who died recently at Haddam, Conn., the Yale Medical School will receive $25,000.

Dr. Simon Flexner, director of the Rockefeller Institute, has been appointed Huxley Lecturer for the current year. This lecture will be given before the Charing Cross Hospital Medical School, London, on October 31, 1912.

Dr. Edna S. Valentine has been appointed third assistant bacteriologist and Dr. Aaron Barlow fourth assistant bacteriologist in the Philadelphia Bureau of Health.

Dr. Don R. Joseph, formerly associate in Physiology and Pharmacology at the Rockefeller Institute, has been appointed Associate Professor of Physiology at Bryn Mawr College.

Dr. Frederick J. Birchard, formerly assistant in Chemistry at the Rockefeller Institute, has been appointed a research chemist in the Dairy Division of the Bureau of Animal Industry, Washington, D. C.

Harvey Society.—The following provisional program of lectures, subjects and dates for the season 1912-13 has been arranged: Oct. 5, Prof. Max Rubner, University of Berlin, "Modern Steam Sterilization." Nov. 9, Prof. Joseph Erlanger, George Washington University, "The Localization of Impulse Initiation and Conduction in the Heart." Nov. 23, Prof. G. N. Stewart, Western Reserve University, "The Rate of the Blood-flow and the Vasomotor Reflexes in Disease." Dec. 14, Prof. F. B. Mallory, Harvard University, "The Infectious Lesions of Blood-Vessels." Jan. 18, Maj. J. J. Russell, U. S. A., "The Prevention of Typhoid Fever." Feb. 15, Prof. Theodore C. Janeway, Columbia University, "Nephritic Hypertension: Clinical and Experimental Studies." March 1, Prof. Edward C. Conklin, Princeton University, "The Size of Organisms and Their Constituent Parts in Relation to Longevity, Senescence and Rejuvenescence." March 22, Prof. John Howland, Johns Hopkins University, "The Scientific Basis for the Artificial Feeding of Infants."

National Association for the Study of Pellagra.—The second triennial meeting of this association will be held at Columbia, S. C., on October 3 and 4, 1912. The preliminary program contains forty-one titles of papers to be read, and in addition it is stated that papers are expected from thirty other contributors, the titles of whose communications are not yet announced. The announced and expected contributions are from authorities in England, Italy, France, Austria, Spain, Rumania, Algiers, Egypt, the Philippine Islands, the Panama Canal Zone, Mexico, Brazil, the Argentine Republic, Cuba, Porto Rico, and the Bahama Islands. Further details may be obtained from the Bureau of Information, Main Street, Columbia, S. C.

Foreign Lecturers at the Post-Graduate Medical School.—Prof. H. Strauss of Berlin will lecture at the New York Post-Graduate Medical School and Hospital, on October 12, 14 and 15, on the Diseases of the Stomach and Kidney. Professor Carl von Noorden, of Vienna, will also deliver a series of lectures on the Pathology and Treatment of Diabetes, Radium Therapy, and Arteriosclerosis at the same place, on October 28 to October 31 inclusive.

Appointments at the Rockefeller Institute.—The Board of Scientific Directors of this institute announce the following appointments: Michael Heidelberger, Fellow in Chemistry; Linda Bartels Lange, Fellow in Pathology; Florentin Medigreceanu, Assistant Resident Physician.

The Texas State Medical Law.—It was stated recently in this column that the Texas State Medical Association is preparing to petition the legislature for a medical examining board consisting of seven members, composed of all schools of medicine. Dr. Holman Taylor, secretary of the association, writes that Texas has such a law already on her statute books and it is one of the best medical practice acts in the United States. This law was enacted in 1907 and the results following its operation are more satisfactory than they could possibly be with any other plan, except, possibly, the single board composed of regular physicians alone, and covering all phases of the practice of medicine.

Obituary Notes.—Dr. W. J. McGee, a well-known geologist and anthropologist in Washington, died on September 4 at the age of 59 years. He was born on a farm in Dubuque County, Iowa, and while doing farm work studied Latin, mathematics, astronomy, surveying, and law. Later he studied geology, archeology, and ethnology. He was for a time attached to the U. S. Geological Survey, later was in charge of the Bureau of Ethnology, from which he resigned to take charge of the department of anthropology at the St. Louis Exposition. He was president of the American Anthropological Society, and had held many other positions of honor and merit in connection with the sciences in which he was so prominent. His wife was Dr. Anita Newcomb McGee, the only woman holding a commission as Lieutenant in the U. S. Army; she organized a corps of women nurses for the army in the Spanish-American war. Dr. McGee bequeathed his brain for examination to Dr. E. A. Spitzka of the Jefferson Medical College of Philadelphia. The weight of his brain was a fraction over forty-nine ounces.

Dr. Charles D. Cook, a retired Brooklyn physician, died of apoplexy yesterday at his home, in his eighty-seventh year. He was born in Hardwick, Mass., and was graduated from the Castleton College of Medicine at Castleton, Vt., in 1853, and two years later settled in Brooklyn and had been in active practice there until 1908. He was a charter member of the New York Institute of Stomatology and a member of the Kings County Medical Society, the American Association for the Advancement of Sciences, the National Geographical Society and the Odontological Society of Great Britain.

Dr. Ernest H. Sparrow of Cambridge, Mass., a graduate of Harvard Medical School, in 1910, died at his home on August 27, aged 32 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent)

WINTRY SUMMER—INSURANCE CAMPAIGN—VITAL STATISTICS—ANOTHER LOW BIRTH RATE—THE R. A. M. C.—TRAINING AND AMBULANCE WORK—NOTIFICATION OF CEREBROSPINAL FEVER—ITEMS—OBITUARY.

London, August 23, 1912.

The abnormal weather has been the most prominent topic of the week among all classes. The effect of the cold and wet on the public health is a subject of speculation, but the injury to the crops is obvious. Yesterday was the finest day of the month; seven hours of socalled "bright sunshine" were recorded for London, but it was cold, only 64°F. at the highest, and in the afternoon there were signs of backing toward rain, which fell in the night and is falling all to-day. The next most insistent topic is the Insurance Act. As it affects all classes, there are protests in all directions. A league of resisters has been formed, said to have already reached three or four thousand members. In one county the farmers have declared they will defy the act. In other parts large employers are refusing to comply in order to force a case into the courts. The Government has responded and already three summonses have been decided by the magistrates, and appeals are going to the higher courts. Much is made of the inequalities as flagrant instances of injustice. A favorite example is that the Chancellor of the Exchequer with his £10,000 a year can keep half a dozen servants for his insurance tax of £3.18.0. But a small manufacturer who can only make £1,000 a year, employing 100 men to do so, is to be mulcted in £119.3.4 for insuring them. A house surgeon inquiring about his honorarium has been informed officially that he must pay unless it exceeds £160 per annum. Cricketers have been told that those who play for money must pay as manual workmen on what they earn by their sport. Footballers are so classed, too, though it sounds rather odd.

The profession continues as a whole united against the act, as must be obvious to the Government in the many resignations and refusals to accept offices under it. The British Medical Association is widely supported in its pledge, and other societies are adopting similar movements. Thus it is proposed to decline to support the Government at the assembling of the territorial force. On Wednesday a Provisional Medical Committee for Cardiganshire unanimously passed a resolution calling on all practitioners acting as medical officers on the territorial force to resign their commissions. It was strongly urged that so long as ministers are determined to work the act in a way to cripple the profession, medical men should not leave their practices and go into camp on terms involving financial loss.

On Wednesday there was put in circulation a summary return by the Registrar-General of the vital statistics collected under his authority for the year 1911. This shows another low birth rate—a subject much discussed of late—and already a number of writers are dealing with the figures. The population of England and Wales in the middle of the year, on the assumption that the rate of increase has remained as in the last intercensal period, is estimated at 36,163,833. The births numbered 881,241, a proportion of 24.4 per 1,000. This rate is 7 per 1,000 below that of the previous year and that was the lowest on record. The rate varied in different counties between 31.1 and 18.2. In the 77 great towns containing more than 50,000 inhabitants (at the census of 1901) the births numbered 411,666, equal to a rate of 25 per 1,000.

London requires distinct consideration, not only for its size and importance, but various circumstances complicate its statistics of births, and also of marriages and deaths. The population had shown a decline in the intercensal period of 1901 and 1911. In the middle of the latter year it is estimated to have been 4,521,301. The marriages in 1911 were 40,201, equal at that estimate to a rate of 17.8 per 1,000 of the population at all ages. This is an increase of 0.5 over the rate of 1910, and of 0.4 over the average rate of the five years 1906-10. The births registered in the year were 111,738; that is, after the registration as far as could be of those occurrring in the chief institutions admitting maternity cases. The number gives a rate of 24.8, which is the lowest recorded in the metropolis. It is the same as for the whole of England and Wales as stated above.

Circumstances which interfere with the statistics in the metropolis are far more obvious in regard to deaths than to births. As an example, no less than 2,826 deaths of London residents took place outside and 3,299 nonresidents inside the boundaries of the County of London. Making the necessary correction for these, it is estimated that the rate was 15.0 per 1,000 in 1911, which is 1.3 above that of 1910 and 0.1 above the average for the previous five years. What is called Greater London includes

all Middlesex, parts of Essex, Surrey, and Kent, with the boroughs of Croydon and West Ham. In this great area the rate was 13.8 and in its outer ring alone it was only 11.8. The figures for infantile mortality in Greater London were 124 per 1,000 births, as against 108, 102, and 95 in the three preceding years. In the County of London the infantile mortality was 129 and in the outer ring alone it was 115.

In connection with the military maneuvers the Royal Army Medical Corps has gone through exercises as to tending wounded in the firing line and passing them by hospital train to the base and to a clearing hospital. Three field ambulances, fully equipped, have been used, each with 10 officers, 240 men, 22 vehicles, and 100 horses. A battle was arranged between infantry brigades, and certain men ordered by their officers fell out while marching, forming casualities for the R. A. M. C. Each man carried an identity disc and in a pocket a first field dressing to be ripped out for first aid. Removal by stretcher squads to a field dressing station is the next step: then by horsed ambulance to tent for surgical treatment, further removal to clearing hospital, and thence by ambulance train to base hospital.

The value to the R. A. M. C. of exercises of this kind is generally pronounced considerable, and the manner in which they were performed is attracting commendation. Some criticism of the system is, however, being made. For example, as at present constituted the R. A. M. C. is not self-contained, but depends on the Army Service Corps for horses and drivers, receiving them only on mobilization. Each ambulance is then supplied with 47 Army Service Corps drivers, 86 horses, and 24 wagons, but a clearing hospital at the field remains immobile until furnished with transport by the officer in charge of communications; consequently it might happen that such hospital would be in an awkward position should the transport service be at a distance or completely occupied. The suggestion is therefore made that it would be an improvement for the R. A. M. C. to have its own transport and so be complete in itself during peace and organized always in war units like other troops.

The local Government Board has sent a circular to health authorities to put in operation the regulations as to the notification of acute poliomyelitis and cerebrospinal fever, under the Public Health Acts.

Many practitioners are foregoing their usual annual holiday, partly on account of the unfavorable weather, but more probably from the difficulty of finding substitutes. It is commonly reported that a locum tenens is more exacting than ever and prefers a temporary post in some pleasant country or seaside locality to close work in towns, while young men who can afford it take a trip abroad before settling in practice. I suggested to one complaining, that an annual holiday was not absolutely essential to health, and my statement being ridiculed, I pointed to the many bed-ridden patients who survive for years.

A radium syndicate is in treaty for the purchase of the Bath springs and mineral water establishment with the Roman remains and exclusive rights to develop them. The City Council will probably lease them all under proper safeguards. The syndicate is willing to spend a quarter of a million on developing the radium water springs of the bathing resort.

The death is announced of Sir William J. Sinclair, Professor of Obstetrics in Manchester University and Physician to the Southern Hospital for Women and Children. He was ex-president of the North of England Obstetrical and Gynecological Society, of the Manchester Medical Society, Honorable Fellow of American and Austrian allied societies, and held many other distinctions. He was an Aberdeen graduate in arts and medicine, 1873-5, with highest honors in both. He contributed to the societies and journals ten successful cases of cesarean section, a paper on this operation under cocaine, and an article on malignant diseases of the uterus in Allbutt and Clifford's system. He took an interest in public matters and was the first chairman of the South Manchester Liberal-Unionist Association.

Dr. T. F. Gardner, Physician to the R. West Hants Hospital, Bournemouth, died on August 1, just after his return from his summer holiday. He was president of the Medical Society of Bournemouth, where he practised many years, and of the Balneological Section of the Royal Society of Medicine.

A verdict of accidental death was found on the 17th at an inquest on the body of Dr. John Wade, Lecturer on Chemistry at Guys Hospital. He died at Sevenoaks Cottage Hospital, to which he was taken on July 28, having met with an accident when riding his motor-cycle in that neighborhood. Coming into collision with a trap, he was struck on the chest by the shaft, breaking three ribs. Pneumonia followed, from which he was recovering when he died from embolism on the 15th inst.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

SOCIAL CAMPAIGN AGAINST ALCOHOLISM—ABUSE AND DANGERS OF RADIUM THERAPY IN ANGIOMA—TREATMENT OF GONORRHEAL EPIDIDYMITIS WITH RADIOACTIVE EARTHS—GENITAL IMPOTENCE—OBITUARY, DR. VILLEMIN.

PARIS, September 2, 1912.

THE Council on Hygiene of the Department of the Seine has just received a communication from the National League for the Suppression of Alcoholism, asking that the legislative bill limiting the number of saloon licenses be submitted as soon as possible to the Chamber of Deputies. Quite recently a similar bill had been introduced by the Government, but unfortunately the discussion over it led to no decision. For this reason the National League for the Suppression of Alcoholism has registered its stern protest, asserting that this question is of vital importance from the viewpoint of public health. Chronic alcoholism in France is indeed a veritable social disease—a scourge comparable to the plague in India. As so well expressed by Profesor Letulle, alcohol fills the prisons with criminals, the asylums with madmen, and the hospitals with consumptives. Unfortunately those who are engaged in the liquor industry have an all-powerful influence, and have prevented the fruition of the Government's project. The large number of saloons is one of the chief causes of the perpetuation of alcoholism, providing the ready temptation to those who are addicted to drink. The contagion of example rapidly spreads. Official statistics show that during the past forty-five years the number of saloons has increased fourfold. It is important that those who are not yet confirmed victims should be shielded from the numerous temptations. For

this reason the Council on Hygiene of the Department of the Seine has unanimously declared that the public authorities should restrict the number of saloon licenses.

The abuses and dangers of the radium treatment of angioma was the subject of a discussion before the Surgical Society. Professor Kirmisson is not opposed to this method, but he calls attention to its abuses and dangers. He cites the case of a fifteen-month-old baby girl in whom the surgical extirpation of an angioma would have been a very simple matter, but in whom the radium treatment has resulted at the end of five months in the production of an extensive ulceration which does not respond to treatment. Another case was that of a young girl in whom a large angioma of the left cheek was treated by means of radium. As the result of this treatment the entire lower lip was completely destroyed. The mouth was gaping, showing the border of the lower alveolar process, the tongue, the sublingual region, and the inner side of the cheeks. Kirmisson believes that these facts are worth communicating, for they show the powerful action of radium on the nutrition of the tissues and the dangers which accompany its use. Pierre Delbet believes that radium provides an excellent form of therapy, the indications and technique of which must be understood. He mentions the case of an unfortunate woman who had a diffuse angioma of the cheek. Following the applications of radium there resulted crusty ulcerations and scaly thickenings of the epidermis, and the patient was much worse than before the treatment. The speaker believes that in the case of subcutaneous angiomata the radium which may be introduced beneath the skin gives excellent results.

The treatment of gonorrheal epididymitis by means of radioactive earths was the subject of study by de Beurmann, Regnault, and Cottin, who reported their results before the Medical Society of the Hospitals. In spite of the considerable attention that has been paid to this subject the treatment of gonorrheal epididymitis is still far from producing satisfactory results. During the past few years there have been utilized in the treatment of gonorrheal arthritis various radioactive earths containing salts of uranium. It has been but a step to apply this treatment in the case of gonorrheal epididymitis. The results obtained have been quite satisfactory. The application of the radioactive earths has caused disappearance of the pain and swelling. The action has been all the more favorable the more acute and recent the inflammatory condition has been. The technique of applying this treatment is as follows: Vaseline is rubbed on the scrotum in order that erythema may be prevented. A thick layer of radioactive earth mixed with glycerin to prevent drying is spread on a compress. According to Ramsay, when the radioactive earths lose their absorbed moisture the emanations are no longer produced, and the curative powers are no longer in evidence. The cataplasm of glycerinated earth is applied to the affected testicle by means of a cotton suspensory covered with rubber tissue, which retards the desiccation of the medicament. At the same time the suspensory causes gentle compression. The application is renewed every twenty-four hours.

Genital impotence was the subject of a prolonged and interesting discussion before the Medical Society of Paris. According to Lefur this condition is a most unfortunate calamity, the prevention and cure of which should be mastered by the physician. Genital impotence may be defined as the inability to accomplish the sexual act. In man this occurs in the organic diseases of the nervous system—tabes, paresis, and disseminated sclerosis; in the neuroses such as neurasthenia; and in diseases of the genito-urinary system as the result of local lesions. It is also present in diseases of nutrition, such as obesity, and in certain modifications and deviations of the genital function. The treatment depends upon the cause. In impotence associated with organic diseases of the nervous system, it is necessary to attend to the primary condition which in most cases is syphilis. In the case of impotence caused by the neuroses, moral and psychotherapeutic measures frequently produce surprising results. In the case of impotence associated with local genitourinary lesions, the treatment of these is first necessary. Impotence caused by diseases of nutrition is combated by attending to the causal albuminuria, dysuria, etc. The opotherapy recommended by Brown Séquard gives excellent results. This treatment consists in the subcutaneous injection of orchitic extract in doses of 2 cubic centimeters every two or three days. After the tenth injection the treatment is suspended for eight days. In some cases prostatic extract may be substituted for the orchitic extract.

Luys believes that a large number of cases are the result of lesions of the posterior urethra left after a badly treated gonorrhea. The diagnosis of these lesions may be made with the aid of the urethroscope, which also permits of the application of an effective local treatment. Berillon believes that frequently impotence is of psychic origin, and that in this case hypnotism may be employed with advantage. Dartigues believes that a large number of cases are caused by sexual intercourse with women in whom there is a relaxed or torn perineum left after childbirth, and that perineorrhaphy is almost as important for the man as for the woman. Guelpa states that impotence which is not the result of an organic lesion may be attacked by means of a treatment of detoxication; purgation and starvation cause the cells to get rid of their toxic products which inhibit the physiological activity of the cells.

Villemin, surgeon of the hospitals, has just died suddenly and prematurely. He inherited the name of one who was the first to demonstrate the true nature of tuberculosis. He was much interested in the diseases of children. His great gentleness and kindness won for him the confidence of all. Three years ago at the bedside of a patient he was stricken with an attack of cerebral hemorrhage. For one year he bore without murmur a left-sided hemiplegia, but he gradually recovered the use of his limbs and was able at last to walk and to wield the scalpel. Death seized him brusquely while he was peacefully at work in his laboratory.

Bilateral Edema of the Ethmoidal Septum in Sinus Suppuration.—D. McKenzie reports the case of a young man who illustrated a type of septal edema. The ethmoidal portion of the nasal septum on both sides presented a smooth, rounded, and boggy swelling, which on the right side was so considerable as to occupy the whole of the upper meatus of the nose. Microscopical examination showed that the swelling was due to simple inflammatory edema.—*Proceedings of the Royal Society of Medicine.*

OUR CANADIAN LETTER.

(From Our Own Correspondent.)

TYPHOID FEVER IN OTTAWA—BIRTH AND DEATH RATES IN MONTREAL—COCK CROWING AND CATERWAULING AS PUBLIC NUISANCES—DEATHS FROM DRINKING WOOD ALCOHOL IN NOVA SCOTIA—PUBLIC HEALTH EXHIBIT AT THE TORONTO EXHIBITION—CREATION OF DOMINION DEPARTMENT OF HEALTH PROPOSED—ANTI-FLY CAMPAIGN IN TORONTO.

Toronto, Sept. 4, 1912.

Canada, like the United States, is visited all too frequently by epidemics of typhoid fever. There are few cities of any size in the Dominion in which more or less enteric fever is not present in the autumn and winter months, while Montreal has been almost notorious for its recurring outbreaks of the disease. Toronto again has more typhoid fever by far than should be the case in a well drained, properly sewered modern city with a good water supply. However, in these cities it has been the water supply in fault, and somewhat tardily now the municipal authorities are endeavoring to remedy defective public water supplies. In Ottawa within the past two years there have been significant object lessons as to the need for insuring water free from infectious germs. An epidemic of typhoid fever broke out there some months ago, the origin of which was clearly shown to be infected water. Advice was given by Dr. Charles Hodgetts and other experts with regard to the steps to be taken to avoid future epidemics. Whether the city authorities neglected this advice or whether the suggestions were only partly carried out, the fact remains that a very serious outbreak of typhoid fever occurred in Ottawa six weeks or so ago. Up to the time of writing there have been over one thousand cases, with about forty-six deaths. The outbreak was extremely explosive, all the cases occurring within the course of three or four weeks. Perhaps the most notable feature in connection with the epidemic is that it originated in the summer, thereby upsetting preconceived notions of the seasonal occurrence of the disease, but emphasizing the fact that whenever there is a defective point in a public water supply an outbreak of enteric fever will follow upon the infection reaching the source of supply. Dr. Charles Hodgetts, medical advisor to the Canadian Commission of Conservation, has been engaged by the Ottawa City Council to prepare a report on the recent epidemic, and Major Drum has been asked to cooperate in the preparation, while Dr. G. G. Nasmith of Toronto has been engaged to give special evidence in reference to the hypochlorite treatment of water. The report should be of value and it is to be hoped that it will show as far as is possible the proportion of paratyphoid fever cases to those of true typhoid. Judging from the relatively small mortality rate in this most recent epidemic of enteric fever, it would seem that many of the cases should be classed with the paratyphoid group.

Montreal has long been celebrated for its high birth rate, and, on the other hand, has gained an evil reputation for its high death rate, mainly amongst young children. Dr. L. Laberge, Medical Officer of Health of Montreal, is now about to publish his report for 1911 and has given out to the lay press some figures which will be included therein. The total number of deaths in Montreal in 1911 was 9,974, which, basing the calculation on the official census return, by which the population of the city is shown to be 478,480, gives a death rate of 21.10 per 1,000. The births in Montreal last year numbered 17,637, which gives a rate of 37.40 per 1,000.

Recently there have been numerous complaints in Montreal with regard to noisy cockerels and howling cats. It appears that some of the inhabitants of Montreal are of decidedly rural tastes and that their bucolic sentiments carry them so far that they endeavor to form a *rus in urbe* by keeping even in flats fowl of various kinds, such as hens, cockerels, geese, and turkeys. The cackling of the hens in the early morn is annoying to those dwelling in neighboring flats, but the vociferous, persistent, and lusty crowing of healthy cockerels is almost beyond the limit of the powers of human endurance. Accordingly, the Medical Officer of Health has been petitioned to indict as a nuisance the keeping of cockerels and other fowl in the heart of the city. The Officer of Health is placed in somewhat of a quandary, as, although he fully recognizes the validity of the claim of citizens to be defended from noisy fowl, so far as he is concerned he can only take action when the obnoxious birds may be regarded as creating an unsanitary nuisance. Still, every citizen has a right to take action under the common law to suppress a nuisance, and there appears to be no doubt that the offensive "rooster" crowing comes under that head. As for the nuisance of cats by night, the citizens of every city of the world are only too painfully aware of its existence. If the Medical Officer of Health of Montreal can discover any means whereby this horror can be abated or done away with, he will gain the undying gratitude of city dwellers everywhere.

Eleven deaths and one case of blindness occurred in Nova Scotia some few weeks ago among Russians who were sold liquor made from wood alcohol.

A feature of the Toronto Exhibition has been the public health exhibit of Ontario arranged by Dr. J. McCullough, Chief Medical Officer of Health of the Province of Ontario. The exhibit is almost, if not quite, the most popular of the Exhibition, an immense amount of interest being taken in the puppets representing the rate of infantile mortality in Chicago and the danger to health of children from sleeping in a vitiated atmosphere. The whole exhibit is educative in a high degree, not the least so being the moving picture views illustrating certain phases of public health. The arrangement and control of the exhibit reflects the greatest credit on those responsible and is in keeping with the marked progression in the direction of public health made by Ontario, especially during the past few years.

At the meeting of the Canadian Medical Association, which took place at Edmonton on August 10, 12, 13, and 14 last, and to which I shall refer at some length in my next letter, one event of considerable importance occurred. This was the passage, by unanimous vote of those present at the meeting, of the report on the Department of Public Health for Canada. The sentiment of the meeting was that the need for the creation of such a department is urgent. Furthermore, the Hon. Dr. Roche, Secretary of State of the Dominion, has declared himself strongly in favor of the establishment of a Canadian Department of Health.

In Toronto a very energetic campaign is being waged against flies under the leadership of the able

Medical Officer of Health, Dr. Charles Hastings. As is pointed out in the monthly bulletin issued by the Health Department, the educational effect of the anti-fly campaign is by no means its least valuable feature. Disease will never be prevented effectually until the public has learned how to prevent, and to appreciate intelligently the methods used to bring about this end.

Progress of Medical Science.

3. Progress in the Treatment of the Neuroses. E. W. Taylor.
4. Tuberculosis in the Aged and the Diagnostic Value of Increased Whisper in the Interscapular Space. H. F. Stoll.

1. Acquired Hallux Valgus.—C. R. Metcalf states that hallux valgus refers to an outward displacement of the big toe—largely from mechanical causes—with inward displacement of the first metatarsal bone and hypertrophy and erosion of its head. Bunions and hammer toes often accompany this condition. The longitudinal arch may drop; the anterior arch is nearly sure to do so. Oftentimes symptoms are due primarily to these defects. By non-operative treatment an effort has been made to hold the feet in approximately normal position; in non-aggravated cases this may be done by wearing proper shoes and plates. Other forms of treatment have proved of doubtful merit. Advanced cases demand operation. Fifteen operations, many of them closely allied, have been devised. The operations fathered by Wilson and by Barker have not met with success in the author's clinic. Better results have followed employment of the methods of Porter, Hueter, and Mayo, remembering always that the two latter may subsequently require plates. Other operations have not been tried, so that the value of tendon transplantation, removal of the sesamoids and like details cannot be fairly expounded. Syms' dictum is worth noting: employ different procedures for different deformities. Always operate on the deformity, not on the bursa. Finally, the most acceptable incision, the question of drainage, of splinting, of shoes and other details of after treatment should be carefully considered for the individual case.

2. After History of Cases of Congenital Syphilis.—W. P. Lucas records the following observation that he has made in these cases: (1) The high early death rate. This may be due partly to the instructions not being followed out, but in great measure it must be admitted that this mortality might be lessened to a considerable degree if such cases could be very much more closely followed, insisting on maternal nursing and on continuance of specific treatment, the two cardinal points in the early management of such cases. (2) The high percentage of backward children. No attempt has been made to draw any absolute percentages in such a small number of cases, but it must be clear that something should be done when, out of sixteen children of school age suffering from any congenital disease, eleven are more or less mentally affected. (3) The lack of following up the initial treatment. As history after history shows, treatment was discontinued as soon as the eruption which, in most cases, was what the mother had brought the child in for, had disappeared. The question here, of course, which might be raised is: Is the mother the one on whom the entire blame is to be put, or is this within the field of the medical service? This naturally raises a second question—whether the responsibility for completed treatment rests on the medical service? The author feels that too often it is really the lack of a follow-up system being provided by the hospital, which would hold and keep hold of such cases, and see that they realize the importance and understand the significance of the treatment.

4. Tuberculosis in the Aged.—H. F. Stoll concludes that pulmonary tuberculosis is not an uncommon disease in persons past 60 years of age. It is more prevalent than the mortality suggests, as an acute pneumonia is often the ultimate cause of death. In persons in the latter decades of life the disease is chiefly characterized by its extreme chronicity and by periods of relatively good health. Many people contract tuberculosis each year from the intimate association with some elderly member of the household who has had a "stomach cough" or "catarrh" for "as long as he can remember." The examination of the sputum of elderly people for tubercle bacilli is a much neglected procedure. The recognition of the pulmonary lesion is often difficult as the typical physical signs are frequently masked by some other condition, notably asthma or emphysema. In these cases the key to the diagnosis will often be found in the interscapular space. The detection of bronchial gland enlargement in adults speaks for tuberculosis rather than for chronic bronchitis or emphysema.

3. Blood Pressure in Pulmonary Tuberculosis.—By F. M. Pottenger. (See MEDICAL RECORD, August 3, 1912, page 225).

4. Bubonic Plague Seen at Close Range.—C. S. Braddock states that no plague case should be taken inside the four walls of a house, but should be treated in tents or small temporary pavilions that can be burned and replaced at small expense upon the death of the patient. He has learned this from the Chinese in the island of Puket in the Indian Ocean, who had several acres of land fenced in and a great number of small pavilions with floors raised from the ground and attap roofs to accommodate one patient each. On the death of the patient the body could be cremated and the pavilion destroyed by fire at the same time. This also saves the lives of many nurses and doctors who would perish if attending pneumonic cases in a close room. The English have found it almost impossible to disinfect large stone buildings in Hong Kong, Singapore, Bombay, and Calcutta. Plague recurs in these buildings with terrifying frequency after everything has been done that science can devise. The author attributes this largely to bed bugs and fleas that are not destroyed by the disinfection and fumigation, and also to the fact that the soil itself becomes infected where the tropical sun does not get at it. He has also found that the disease was not transmitted nearly so much if every one was compelled to put on shoes and stockings. All of the soldiers used in quarantine duty, and who were in close contact with plague cases, were compelled to wear shoes

and stockings, and not one contracted the disease. The author was always careful not to stoop too closely over a pneumonic case so as to avoid the breath or coughing of the patient, and also to keep his leggings saturated with coal oil to keep the fleas away. In the town of Petchaburi a great number of children died, and it was found on investigation that the rats having died, the fleas took up their habitat on the dogs, and the children, petting the dogs, suffered in proportion.

5. Cutaneous Sporotrichosis.—G. B. Foster and W. H. Thearle state that many conditions formerly diagnosed as tuberculous lymphangitis, tertiary syphilis, glanders, etc., are now being recognized as sporotrichal infections. Sporotrichosis is widespread, occurring sporadically in man, but it may assume endemic or even epidemic proportions among animals. Infection most frequently occurs in young adult males, but age and sex appear to play no part as predisposing factors other than in their relation to exposing the individual to the sources of infection. Occupation plays an important part, the disease usually occurring among farmers, stablemen, and others who handle stock. The period of incubation, usually seven days, varies from six to twelve days. The symptomatology of the reported cases is strikingly similar. The initial lesion, as a rule on the hand or forearm, follows traumatism which has broken the continuity of the skin. The original lesion may heal before the sporotrichal lesion appears, or it may remain open. The primary sore develops as a nodule or pustule surrounded by a circumscribed area of induration, becomes reddened and boggy, and eventually breaks down, discharging thick, viscid pus. Sloughing follows, with the formation of an indolent ulcer which shows no tendency to heal. Following the initial lesion, similar nodules appear along the lymphatics which drain the part and these, in turn, inflame, soften, and break down. Glandular involvement may be absent, local, or generalized. Constitutional disturbances are not usual, but occasional sensations of chilliness and mild febrile reactions occur in some cases. Recovery almost invariably follows the internal administration of one of the iodine salts, with vigorous antiseptic treatment of the local lesion. Death may occur in the debilitated or as a result of intercurrent infection. Extensive abscesses, the formation of fistulous sinuses, and erysipelas have been noted as complications and sequelæ. A tentative clinical diagnosis of sporotrichosis may be confirmed by demonstrating the specific causative agent, the sporothrix, in smear preparations or cultures from the lesion. The organism is a fungus, consisting of branching mycelia with numerous highly refractive pyriform spores which are not unlike yeast cells in appearance.

9. History of Surgical Hemostasis.—W. C. Borden traces the history of surgical hemostasis to the perfected essentials in the operation of the present day, *i. e.* elastic compression, ligation, and asepsis, and the less important hemostatic measures, such as heat, cold, torsion, and acupressure. In reviewing this history he notes that all the important surgical discoveries in hemostasis were preceded by suggestions or practices of a similar kind which, however, did not become of value until the flash of genius touched them. Genius did not bring forth these facts until other conditions, such as opportunity, and more particularly the progress of invention and the advance of the sciences made their finding possible. Opportunity gave to the acute and courageous mind of Paré the occasion to employ, and the high position authoritatively to recommend the ligature; this was known, but not used, by his predecessors. The advance of anatomical knowledge after Vesalius and the physiological triumph of Harvey in discovering the circulation of the blood, completed the facts necessary firmly to establish the ligature in surgical practice. The invention of rubber made possible Esmarch's advocacy of elastic constriction and its later wide application. The researches of Pasteur led to the investigations of Lister and the establishment of antiseptic and aseptic surgery, and this, combined with the findings of the many workers in pathology and bacteriology, made possible the aseptic ligature and the clean wound, in which repair can proceed unfraught wtih the dangers of inflammation and suppuration, and completing the present day perfection in aseptic control.

3. Pneumococcus Infection and Immunity.—R. J. Cole presents a critical review of the work of the last few years on pneumonia. He considers first the infection or onset—how the pneumococcus lying harmless in the mouth under ordinary circumstances, can bring about the severe infection of the lung. Decreased resistance of the patient as a cause lacks experimental proof, but there is evidence that a changed condition of the lung may permit the pneumococcus to gain lodgment and to grow in its tissues. There may be at first a non-specific exudate dependent on cold, trauma, etc., and pneumoccocci being the organism most commonly present, may set up on this an added irritation. There is much evidence against the old view that lobar pneumonia occurs at once throughout a lobe. Sections of the lung of persons dying from the disease show a constant irregular extension of the process. The clinical features of pneumonia are an acute intoxication, and the author relates experiments of his own to test Friedberger's theory of this in pneumonia, and he does not accept Rosenow's theory of difference of virulence in the pneumococci causing autolysis in one case and not in another. Typical pneumococci always autolyze whether highly virulent or not. An active poison can be readily and constantly produced from the bodies of pneumococci and it may or may not be responsible for the symptoms in pneumonia. As regards the occurrence of the crisis, the development of immune bodies in the blood serum cannot be demonstrated. From clinical observation it would seem much more likely that the crisis represents a kind of neutralization of the intoxication rather than a destruction of the bacteria of the lungs. The crisis is still an obscure phenomenon and it cannot be stated positively whether it represents a destruction of the bacteria, a neutralization of the poison, a kind of anaphylactic shock, or a combination of all of these. Lastly the author speaks of the action of immune serum and specific therapy generally in the lungs. The failure of immune sera in the human subject is laid by Neufeld to the impossibility, or at least the failure, to inject a sufficient amount in proportion to the body weight. Dochez's experiments seem to indicate that there may be another explanation of the failure and that, in addition to the presence of immune bodies in the serum administered, it is necessary for the body of the infected animal itself to play an active part and that in case of very severe infection it is unable to react to a sufficient degree. If one

is to make serum efficacious in treatment some method of increasing this completing action of the body must be found, and one may be able to obtain curative results by combining active immunization, that is, vaccination, with the supplying of immune bodies by immune serum administration. It is uncertain whether the use of a polyvalent serum would be better than the univalent one of immune serum.

4. Corpus Luteum Extract.—C. F. Burnam, reviewing the function of the internal secretion of the ovaries and the use of the extract, gives his personal experience in experimenting with the extract of the corpus luteum of the pig. When given by the mouth corpus luteum tissue of the sow, even in large doses, has little or no toxic effect on women. It affords a valuable means of controlling the nervous symptoms which occur in so many patients at the time of the natural or artificial menopause, giving relief to most sufferers. It is a valuable remedy in treating patients with insufficient internal ovarian secretion during the menstrual life. This class constitutes a very large number of women. It is an excellent remedy to induce mentruation in young women suffering from functional amenorrhea. Those who are fat, in addition to regaining menstruation, usually, but not always, lose weight. There would seem to be a possibility for the use of the drug in cases of unexplained sterility and repeated abortions. Extensive use should be made of corpora lutea from the cow, sheep, and other animals to determine if these extracts work more successfully than those of the sow. The ideal luteum tissue for any animal is doubtless tissue from its own species, but this cannot be obtained for the woman So far as it goes, the author's work strengthens his conviction that Fraenkel is correct in attributing menstruation in the internal secretion of the corpus luteum. From clinical experiences he is inclined to believe that the corpus luteum possesses different properties due to different chemicals. One of these substances causes hyperemia of the pelvic organs; another relieves nervous symptoms of a toxic character, as at the menopause. It would seem that this product acts as a neutralizer, since even large doses of the luteum cause no disturbance of a toxic nature. On the other hand, the toxic results of intravenous injections of the luteum extracts, as well as the nervous phenomena of menstruation, show that there must also be some toxic material present which is not absorbed from the stomach or intestines. All of these various substances may in the future be separated.

5. Puerperal Infection.—F. J. Watkins, from a study of recent literature, and also from personal observation, has been impressed with the difference of opinion that exists concerning the treatment of puerperal infection. His investigations indicate that local treatment is too prevalent and that systemic treatment would be advisable in most cases. He finds that most cases are treated by curettage, douches, and intrauterine medication. The author gives his reasons for believing the disease a systemic one and that it should be treated chiefly by general remedies which strengthen the bodily resistance and hasten the development of immunizing bodies. Retained products of conception should be left to escape spontaneously. In individual instances gauze packing should be employed to check bleeding, to hasten separation of the tissues, and to stimulate uterine contraction. Pelvic inflammatory exudates are usually absorbed, but in exceptional cases, usually due to colon bacillus infection, incision and drainage should be employed. Cases of suppurative peritonitis should be operated on early, but the vigorous operative treatment employed frequently is more dangerous than the disease.

6. Treatment of Abortion.—R. McPherson concludes that abortions are more common than is realized and the sequelæ are frequently serious. Rarely, if ever, is an abortion complete. Only in 13.7 per cent. of the cases analyzed was there the slightest reason to believe that the ovum was expelled unbroken. All abortions should be investigated and the uterine cavity explored. When this is done properly, one can show a mortality in all classes of cases of not more than 1.8 per cent. and in ordinary cases, exclusive of accidents and malignant complications, of not more than .016 per cent. One can always show, which is perhaps most important of all, satisfactory results in 97 per cent. of all cases so treated.

7. Gynecological Disease in the Insane.—F. J. Taussig calls attention to the following three facts (1) The decidedly greater frequency of gynecological disease in manic-depressive insanity—74 per cent. as compared with the average of 47 per cent. (2) The large proportion of chronic inflammatory conditions of the genital tract in this form of insanity. (3) The proportionately large percentage of mental recoveries after gynecological operations done on women having this form of insanity. In manic-depressive insanity every patient should be subjected to a gynecological examination, and when a definite lesion is found this should be corrected either by local or operative measures.

3. The Use of Tuberculous Tissue Products in the Vaccine Treatment of Surgical Tuberculosis.—J. Fraser and J. P. McGowan, acting on the supposition that while artificially prepared tuberculins may contain many of the toxic substances responsible for the pathological changes present in a tuberculous focus the whole of these toxic substances would be most likely obtained in tuberculous foci as they occur in the naturally infected human body, have used such material for the preparation of a vaccine. In short, instead of using artificial media for the growth of the tubercle bacillus in the preparation of vaccinal material, the products occurring where human tissues have acted as the culture medium have been employed. Further, the authors have made as far as possible the vaccinal treatment autogenous, using the patient's own tuberculous material, obtained at an operation or otherwise, as the source of the vaccine. In some cases this was impossible as no operation had been performed, and in such instances material from other patients was used; but bone cases were always treated with material from bone tubercle, and gland cases with material from gland tubercle. The technique used was as follows: A portion of tuberculous tissue—preferably caseous—was taken at the operation and ground up in an agate mortar with washed silver and saline was then added, and the emulsion was allowed to stand for an hour to allow the grosser particles of the sand and tissue to settle. The supernatant fluid was then centrifuged to get rid of the finer particles. This supernatant fluid was pipetted off and sterilized by heating to 60° C. for an hour. The fluid so obtained was tested for sterility, and finally put up in measured quantities in sterile capsules which were sealed. In the preliminary experiments no attempt was made to accurately standardize the vaccine. The authors began their experiments with a very small

quantity of the vaccinal fluid—5 cubic millimeters—and if the patients did not react too severely the next dose, which was given a week after, was increased to 10 c.mm., and so on with increments every week of 5 c.mm., until at the end of ten weeks a dose of 50 c.mm. was given. In one case only was there a severe reaction to a 5 c.mm. initial dose. In this case the dose for the first few weeks was kept at 5 c.mm., the reaction becoming less severe with each injection, and in the end the dose was increased as in the other cases without severe symptoms developing. The most encouraging results are seen in gland tubercle, the reason probably being that, from their greater accessibility to clinical examination, improvement was more readily detected. Even more striking than the local improvement has been the general change. Another noticeable feature is the rapidity with which improvement has made its appearance; in one case only has the treatment exceded ten weeks. An improvement begins to be noticeable usually after the third inoculation. As regards disadvantages there are possibilities of two. In one instance the general reaction was severe enough to prevent the progressive increase in dosage which one aims at, but in such circumstances a repetition of the smallest tolerable dose induces an immunity which soon permits the use of the larger amounts. The second disadvantage is a local one—the treatment undoubtedly induces a considerable focal reaction. This may lead to the formation of abscesses and caseation, but the exhibition of minute doses is sufficient to prevent such a complication.

4. **Nerve-Ending Anesthesia.**—C. Clarke states that a 0.6 per cent. aqueous solution of beta-eucaine hydrochloride injected hypodermically has an immediate anesthetic effect on sensory nerve endings, while the nerve cords and fibers passing through the infiltrated area retain their conducting power unimpaired for some considerable time after the injection. During the course of many operations the surgeon divides comparatively few nerve endings, considering the size of the wound, for the knife cuts a cleft which afterwards gapes and exposes the tissue or organ to be operated upon. The primary objects of nerve-ending anesthesia are concentration and economy of anesthetic, for the actual quantity of beta-eucaine which can be safely injected into a patient is limited to about 6 or 7 grains. For the operation the tissues are first desensitized and then divided in successsive layers. No interval need elapse between the injection of the anesthetic and the commencement of the operation, for beta-eucaine in 0.6 per cent. strength acts on sensory nerve endings practically at once. The chief points to be observed when using beta-eucaine hydrochloride in 0.6 per cent. strength as a nerve-ending anesthetic are: (1) Inject the anesthetic freely in the actual line of the incision; (2) keep strictly to the infiltrated tissues; and (3) operate immediately after the injection.

5. **The Nature of Colon Bacilluria.**—E. M. N. Williams believes that colon bacilluria is a late stage in a chronic disorder of the intestine, and that by traversing diseased intestinal walls the organism usually gains access to the urinary tract. The short straight female urethra has been supposed to offer facilities for an ascending infection, but it must be remembered that women are more subject than men to constipation, and therefore to the conditions dependent upon it.

1. Further Experience of the Specific Curative Action in Amebic Disease of Hypodermic Injections of Soluble Salts of Emetine. L. Rogers.
2. Granule-Shedding in *Trypanosoma Gambiense*. H. S. Ranken.
3. The Results of Sanatorium Treatment. F. W. Burton-Fanning and W. J. Fanning.
4. A Note Upon the Use of Antiformin in Sputum Examination, and on Staining Methods for the Demonstration of Tubercle Bacilli. G. H. K. Macalister.
5. The Pikrin Method of Staining Tubercle Bacilli. H. Wilson.

1. **Hypodermic Injections of Soluble Salts of Emetine in Amebic Disease.**—L. Rogers concludes that his method of the subcutaneous injection of soluble salts of emetine is a specific treatment of amebic hepatitis and amebic dysentery. The treatment is so rapidly beneficial in the latter as to be also of great diagnostic value between that and other causes of the passage of blood and mucus in the stools. Yet, strange to say, this remarkable remedy, according to the author probably the most active specific in the whole range of medicine, not excluding quinine and salvarsan, has for long been thrown away by those who pinned their faith in ipecacuanha sine emetina.

2. **Granule-Shedding in Trypanosoma Gambiense.**—H. S. Ranken states that the "infective granule" of trypanosomiasis occurs in *T. gambiense* in cases of sleeping sickness. Granule shedding has been observed, and the free granule has been seen in lymph glands and internal organs—liver, spleen, and lung. The granule is at first pyriform, but develops a flagellum. It is actively motile, and can be distinguished from "blood dust."

3. **End Results of Sanatorium Treatment.**—F. W. Burton Fanning and W. J. Fanning state that the first three years after sanatorium treatment are the crucial period. The patients who survive that time possess a greater expectation of maintaining their ascendency over the malady. Among the cases observed by them the authors note that during the first triennium after residence in the sanatorium there died 50.7 per cent. of the patients. During the second triennium there died 7.1 per cent. The authors are convinced that the results of the sanatorium treatment of pulmonary tuberculosis promise to become better and better. Attention must be concentrated on the early diagnosis of the disease. Experience has shown that the early consumptive does not discover himself, but must be actively sought out, and that for this work the service of an expert is required. At present the applicant for admission to a sanatorium is provided with a form certifying to the presence of more or less glaring physical signs in his chest. One should aim instead at utilizing the sanatoria for patients certified to have no physical signs of lung destruction.

4. **The Antiformin Method of Sputum Examination.**—G. H. K. Macalister concludes that by means of treating with 25 per cent. antiformin 1,651 samples of sputum found negative as a result of the direct examination, it was possible to demonstrate the presence of tubercle bacilli in 9 cases, that is to say in 0.54 per cent. of cases. This figure, though small in comparison with those obtained by other workers, is large enough to justify the use of this reagent when a large number of specimens are examined. The discrepancy between these results and others is possibly due to the detailed care which is expended upon the direct examination.

5. **The Pikrin Method of Staining Tubercle Bacilli.**—H. Wilson notes that this, which is also known as Spengler's method, is simple, and is conducted as follows: Having made a suitable film—(1) Stain with carbol fuchsin, warm, but without too much heat. (2) Pour off the stain without washing. (3) Pour on picric acid alcohol (consisting of equal parts of saturated solution of picric acid and absolute alcohol); after three seconds—(4) Wash with 60 per cent. alcohol. (5) Treat with 15 per cent. nitric acid till yellow (thirty seconds). (6) Wash again with 60 per cent. alcohol. (7) Counterstain with picric acid alcohol till lemon colored. (8) Wash with distilled water and dry gently at a low heat. With a little practice this will be found an easy and quick method, and the extra time involved in the staining will be more than compensated by the ease with which the bacilli are found if present, and the consequent less time spent at the microscope. This applies particularly to urinary sediments.

Splanchnomegaly with Acromegaly.—Amsler mentions the difference of opinion as to the nature of this association. While one sees a primary splanchnomegaly, coordinate with acromegaly, others regard the former as secondary to the latter and due purely to stasis and increase of connective tissue. It is, of course, possible that true hypertrophy may be associated with this secondary hyperplasia. At an autopsy by the author were found acromegaly, tumor of hypophysis, enlargement of the tongue, spleen, kidneys, and liver. The testicles showed involutional changes, and a goiter was present. The heart was dilated and hypertrophied. There were choked disks and retinal hemorrhages. The abnormal tissues were all submitted to microscopic examination. The hypophysis tumor was found to be an eosinophile adenoma of the anterior lobe. The heart was in brown atrophy, and the hypertrophy was evidently primary, as neither arteriosclerosis nor valvular disease was present. The spleen was also the seat of primary hyperplasia. The adrenals showed hyperplasia of the cortical portion. The enlarged kidneys showed neither stasis nor fatty alteration, and the increase in size was due to hyperplasia of the glomeruli and tubules. The state of the enlarged liver was chiefly one of hyperplasia with a certain amount of hypertrophy. There was a slight enlargement of the pancreas, due to hyperplasia of Langerhans islets. Other histological finds were not important. The author, therefore, feels confident that the splanchnomegaly is not secondary to stasis, but while due evidently to primary hyperplasia the nature of the latter is obscure, although it may be considered as akin to the acromegaly itself.

Recent Results of Research in Tropical Medicine.—Hoffmann mentions first the spirochetotropic action of salvarsan in frambesia, relapsing fever, and ulcus tropicum. In all of these affections the new remedy exerts the same brilliant specific action as in syphilis. The affection known as venereal granuloma, a new venereal disease studied in South America, has been found to show noteworthy analogies to rhinoscleroma. The cause is not a spirochete, as has been claimed, and salvarsan has entirely failed to cure or favorably affect the disease. The affection known as parasitic thyreoiditis has been found to be due to a trypanosome, for which the big bedbug or conorhinus acts as host. The affection has therefore been styled coreotrypanosis (kopsis-bedbug). Much work has been done in the comparatively new field of the leishmaniosis. It has been learned that the so-called pian boil or Surinam yaws, long regarded as frambesia, is due to a leishmania introduced by a tick and hence is a congener of the Aleppo boil. Pellagra now seems to be attributable to a simulium or sandfly which acts as host for an unknown microorganism. The food theory has almost been abandoned. A similar etiology is being agitated for beriberi, although insufficient diet may furnish the predisposition if not the actual causation. Verruca peruana makes one more dangerous disease to be traced to an insect or tick host. The latter is not yet known, but is evidently one of nocturnal habits. We now know that this affection may occur in a benign form. The incubation period is three weeks. The actual cause is doubtless a hematozoa. Variola is now fully recognized as a perennial disease in certain regions of the tropics and one which slays an immense number of people. A stable vaccine is indispensable and any detail of technique which will assist in preserving the same will protect in direct proportion to the degree of presentation. The lepra bacillus has been freely cultivated and is seen to be a streptothrix. As far as the bubonic form of the plague is concerned, it is certain that it is exclusively flea borne. No flea, no plague. The anti-rat crusade is, it is to be feared, ineffective in stamping out the disease as a whole, although a useful resource. One should not rest content with rat killing. The best prophylactic is prompt recognition and isolation of the first cases, because fleas quickly spread the disease from man to man.

Deutsche medizinische Wochenschrift.

August 22, 1912.

Thrombosis.—Ribbert states that in the majority of cases thrombosis is due to roughening of the vascular wall, which causes a precipitation of the blood plates. In other cases, secondary in character, unevenness of the first stratum of precipitation is the cause of further deposit. Slowing of the circulation is a contributory factor, for otherwise the bloodstream might wash away the deposit. In regard to the initial roughening of the vascular wall this may be due to a variety of dissimilar lesions. Some of these are chronic—arteriosclerosis, phlebitis, endocarditis, etc., while others are more abrupt, as an infection, an injury, the penetration of tumors. Slowing of the bloodstream is an auxiliary cause in a very large proportion of cases.

Excretion of Diphtheria Bacilli in the Urine.—Conradi and Bierast as a result of personal studies which thus far have been fragmentary conclude that in about one-third of all cases of diphtheria virulent bacilli reach the urine and are often in position to propagate the infection. The danger of direct contact infection is slight because of the great dilution, there being relatively few bacteria present in a given bulk of urine. However, the latter should be disinfected as long as it is infected. Under exceptionally favorable conditions the urine might contaminate the milk vessels and so infect a milk supply. In theory the urine might infect the patient's skin, causing for example, diphtheritic vulvitis.

Mercury as a General Spirillocide.—The efficacy of hydrargyrum against the spirochete of syphilis has influenced Kollé and two others to test it in diseases of similar causation. In fowl spirillosis the disease appears to yield to those mercurials which are of proved value in syphilis. Hence the affection of the fowl may be used as a sort of trial horse for new antisyphilitic combinations. The authors found that the presence of the benzol ring or pyrazolon nucleus in the mercury molecule gave evidence of an active form of remedy. In other words the latter combined an efficient portion of the salvarsan molecule with mercury. The next step was detoxication without impairment of therapeutic efficiency. The ultimate result was a substance sulfamino-dimethyl-phenyl-pyrazolon-hydrargyrum, believed to represent an effective general spirillocide, the chief value of which should of course be as an antisyphilitic.

Combination of Medicines.—Kochmann has investigated this subject from the viewpoint of Bürgi's teachings. As a result he disputes the correctness of the generalizations of the Swiss. He does not find that a minute dose of a synergist will necessarily potentize the ordinary dose of the principal remedy. He does not appear to deny that this phenomenon may be noted under particular circumstances, but the mechanism in different combinations may vary greatly. Hence instead of proceeding upon the supposition of the existence of a general law it will be much wiser to consider each special case as a law in itself, at least for the present. In combining remedies in addition to increasing the force by synergism we also have to neutralize the unpleasant collateral effects, hence the further merit of the special problem viewpoint.

Peculiarities in the Course of Varicella.—P. Merklen has observed in the course of varicella the following unusual complications: enlargement of the lymph nodes, torticollis, and extreme itching. These peculiarities are attributed to an abnormal reaction to the varicella virus.—*Annales de Médecine et de Chirurgie Infantiles.*

Insurance Medicine.

REPORTING OF NON-ORGANIC HEART MURMURS.

To the Editor of the Insurance Department:

Sir:—In regard to the discussion as to reporting all non-organic heart murmurs, I may be permitted to report a single experience. Some years ago I was examiner for a considerable number of leading life insurance companies, until I resigned because of lack of time to give the examinations suitable attention. During that period I examined for a New York company a man who seemed to be a perfect risk except for a slight murmur which I assumed was probably non-organic, but which I reported in my examination with a special letter of explanation and recommendation to the home office. The application was promptly rejected, somewhat to my humiliation. A few days later I received a telegram from a Milwaukee company, for which I was not examiner, directing me to examine the same applicant, and to report directly to them. I repeated the examination and sent the company a copy of my original letter to the first mentioned company. (The murmur was so slight that their local examiner had failed to detect it, but in the meantime they had received the adverse report of the New York company.) The application was held up by this company for a few weeks until the applicant was seen by a special examiner from the home office. He found, as it was later reported to me, just what I found, but recommended the application and the policy was issued.

A little later one of the medical directors of the company in New York, who was visiting the principal agencies, called on me, and we spent a delightful evening together. I brought up for discussion several problems that had presented themselves to me, and among others the matter of heart murmurs. I asked him if in one of these doubtful cases it would do any good to send the applicant, if the case was one of sufficient importance, to the home office, so that the medical directors could examine him for themselves. His reply was that that was unnecessary; that they had a hard and fast rule that no one with any trouble about the heart would be accepted, since no one could tell just what the trouble was, and the organ involved was too important. This statement was, of course, entirely satisfactory and settled the matter.

Within one year the Milwaukee company was called upon to pay the face of the policy. I was never, however, able to learn the immediate cause of death.

J. F. Baldwin, M.D.

Columbus, Ohio.

Interest in the subject of life insurance medicine would be stimulated if others would follow Dr. Baldwin's example by contributing a leaf from their experience, or by offering any criticism occurring to them of statements appearing in these columns.

Dr. Baldwin evidently encountered here one of the many difficulties connected with examining for life insurance. The description of his case has a familiar ring to one devoting much time to the subject, but it nevertheless is one from which a lesson may be learned. The three following points call for special notice.

1. A slight murmur was heard. Since Dr. Baldwin assumed that this was *probably* non-organic, there was some element of uncertainty in the diagnosis at the time, even in the mind of this experienced examiner; therefore the most advisable course to pursue would have been to recommend rejection, notwithstanding the fact that the murmur was subsequently pronounced non-organic by another authority. There should be no question, under all circumstances, as to giving the company the benefit of any possible doubt in regard to the character of cardiac affections. Heart murmurs may be looked upon as *positively* organic, doubtful, or *positively* non-organic. The last of these is of no importance and the *only* kind to be omitted from the report.

2. Doubtful cases will be rejected without hesitation, whether reported by the field or home office examiner. We do not agree with the medical director, however, who assured Dr. Baldwin that it is unnecessary to send applicants with doubtful cardiac conditions to the home office, or even to members of the home office staffs who happen to be in the neighborhood. One of the duties of medical directors is the personal inspection of doubtful or rejected risks whenever possible, and they will, according to our knowledge, always be found cheerfully ready to look over such cases in order to assure their respective companies that no injustice is being done to either the applicants or the agents.

3. The actual cause of death in the case cited would be a most interesting feature, especially as to how far, if at all, it was due to some defect in the circulatory system.—Editor.

Varieties of and Motives for Suicide.—Schilling has recently compiled statistics on suicide in Prussia and the German Empire. Hanging occupied first place during the period 1883-1890, no less an average than 60 per cent. electing that mode of death. Less than 20 per cent. chose drowning, while over 10 per cent. shot themselves. Next in order comes the knife, and after that poison. As for motive, with women it is love and jealousy, with men matters involving their name and honor. Alcoholism is responsible for many suicides. More single than married people slay themselves, more unmarried women than unmarried men, but more widowers than widows. Students and soldiers show a proneness to suicide, and the lower schools have more victims than the upper ones. In Prussia during 1901-1903 there were 1,700 suicides among students, and the ratio should have increased since. In the Prussian army in 1883-1890 there were 36 suicides per 100,000 between the ages of 20 and 25. The enormous increase of suicide in our day gives a shocking picture. In the nineteenth century two millions of Europeans took their own lives. Since 1831 the number of suicides has increased 400 per cent., while the number of people has increased but 60 per cent. During the years 1869-1872 Prussia had 72 suicides per million. During the period 1891 to 1900 the total number was 60,518. In the German Empire during the year 1881 the number was 9,994, in 1903 it was 12,730. Suicide in children is also constantly increasing. In Prussia from 1879 to 1898 there were 1,708 cases, and since then the number has been steadily augmented. The same increase in suicide is to be noted elsewhere, save in Denmark, Norway, and Spain, where the rate is decreasing.—*Deutsche Versicherungszeitung*, No. 85, 1912.

Book Reviews.

Das Subaquale Innenbad. Von Privatdozent Dr. Anton Brosch. Unter Mitwirkung von Dr. Otto von Aufschnaiter. Zweite, vermehrte Auflage. Mit 10 abbildungen im Text. Price: 3 marks. Leipzic und Wien: Franz Deutieke, 1912.

Die Gesundheitskontrolle durch den Organsinn. Von Privatdozent Dr. Anton Brosch. Unter Mitwirkung von Dr. Otto von Aufschnaiter. Zweite, oermehrte Auflage. Price 2 marks. Leipzic und Wien: Franz Deuticke, 1912.

The authors of these two brochures have taken very much to heart Bouchard's famous aphorism that man is a laboratory of poisons, and have gathered numerous arguments in favor of "washing out" these poisons from the organism. They consider that the colon and the rectum are the chief offenders and that all of the present day methods of cleansing these organs are futile. Instead they propose the use of an "enterocleaner," which seems to be nothing but a very cumbersome apparatus for administering a high enema to a patient immersed in a bath. We have not gathered from the text what other motives have prompted the authors to manufacture this apparatus, but their ingenuity certainly deserves a better subject.

Traité International de Psychologie Pathologique. Directeur: Dr. A. Marie (de Villejuif). Comité de Rédaction: MM. les Professeurs Bagenoff (de Moscou), Bechterew (de St. Pétersbourg), Clouston (d'Edinbourg), Déjerine (de Paris), Grasset (de Montpellier), Lugaro (de Modène), Dr. Magnan (de Paris), Pilcz (de Vienne), Ziehen (de Berlin). Tome Troisième. Psycopathologie Appliquée. Par MM. les Prs. Bagenoff, Bianchi, Sikorsky, G. Dumas, Havelock-Ellis, Dr. Cullerre, A. Marie, Dexler, F. Helme, Pr. J. Wertheim Salomonson. Avec 338 gravures dans le Texte. Price 25 francs. Paris: Librairie Felix Alcan, 1912.

This is the third and last volume of this treatise. All three are bulky volumes, the present containing 1086 pages. The others were about equally large. The first was on General Psychopathology, the second on Clinical Psychopathology. The present treats of pathological psychology and opens with an original study by Professors Bianchi and Sikirsky on morbid mentality considered from the psychophysiological point of view. Sikorsky in writing the main part of this article has presented the subject in a most interesting way—at one and the same time ethnical, artistic, physiognomonic, clinical, and philosophic. There are numerous illustrations which depict the expression, attitude, etc., in various intellectual, emotional or volitional states, in various races, in both sexes and at various ages. Physical changes in the respiration, blood, voice, etc., are carefully studied. The methods of physiological and experimental psychology are pursued. An appendix by G. Dumas on "Pathological Sadness and Joy," and another by Havelock Ellis on "Psychopathic Sexuality" add much interest to this part of the work. Following this is a long chapter on comparative psychopathology, in which the question is delightfully treated from various points of view. Cullerre writes on examples of madness in history; Marie on madness in various races and countries; Marie and Bragenoff on collective psychopathology (epidemics of madness, insanity of families, etc.); and Dexler, on mental disorders in the higher types of animals. The book concludes with a chapter on the general causes of psychopathic disorders by Marie; and a chapter on laboratory methods by several authors. This volume, like the two which have preceded it, is of great value and of much interest. The collaborators are all men of authority in their various special fields, active workers and widely known.

Nervöse Angstzustände, und ihre Behandlung. Von Dr. Wilhelm Stekel, Wien. Mit einem Vorwort von Professor Dr. Siegmund Freud. Sweite, vermehrte und verbesserte Auflage. Price 17 marks. Berlin: Urban & Schwarzenberg, 1912.

This is the second edition of an important contribution to psychiatry, treating of the anxiety or fear neuroses. A critical comparison of it wtih the first edition, the author himself states, will disclose the fact that his conception of these neuroses has undergone considerable change. He still believes that the way to their proper understanding is through psychoanalysis; and his therapeutics remain the same. But the peculiar nature of these neuroses, as they appear to him, is disclosed with clearer insight. There is a broader development, perhaps rather than an alteration of the views that were set forth in his first edition. He mentions, also, a more extensive gradation or shading of conditions from the neuroses into the psychoses. The book is divided into three parts. The first is devoted to the anxiety neuroses proper; the second to anxiety hysteria; the third to diagnosis and treatment. The technique of psychotherapy is described. The second edition commends itself to us as affording a broader conception of the subject and of greater interest and value even than the first edition.

Common Disorders and Diseases of Childhood. By George Frederic Still, M.A., M.D. (Cantab.); F.R.C.P. (Lond.); Professor of Diseases of Children, King's College, London; Physician for Diseases of Children, King's College Hospital; Physician to the Hospital for Sick Children, Great Ormond Street; Honorary Member of the American Pediatric Society. Second Edition. Price $5.50. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1912.

This work differs strikingly from the general run of textbooks on diseases of children in the personal note which permeates its pages. There is a wide departure from the stereotyped method of presenting the subject of pediatrics, with the dreary sequence of definition, etiology, pathology, etc. No effort is made to cover the entire subject, the author having been content to draw upon his own extensive experience in describing fully the most important of the diseases of children which the practitioner is called upon to treat. Particularly satisfying is the large space that is accorded to the details of treatment. The following subjects which were not discussed in the first edition are included in the present one: enlarged tonsils and adenoid hypertrophy, epilepsy, asthma, and hydrocephalus. The author's views on infantile paralysis and congenital syphilis have been considerably modified. It is difficult to pick out any one subject whose discussion more than any other displays the keen observation of the mature clinician whose views are not a mere repetition of what others have said and written. The author's attitude with respect to the operative treatment of hypertrophied tonsils and adenoids shows this originality. He decries the use of the fingers as a means of detecting the presence of adenoids. These, even when unmistakably present, and hypertrophied tonsils, need not be removed unless there is some definite evidence of impairment of the child's health, such as the presence of earache, deformity of the chest, etc. The definite risks of operation, the occasional bad sequelæ, the best time for operating, and the necessity of the operation being performed by one specially trained for the purposes are all carefully weighed. The author alludes to the frequency with which asthma occurs during childhood, and shows how many cases of this disease occurring in adults had their beginnings in the unrecognized chest conditions of early life. In discussing the treatment of threadworms the author emphasizes the futility in many of the cases of attacking the condition solely by means of local measures. Among the other topics exhaustively and entertainingly described may be mentioned the following: curd indigestion; flatulency and colic in infancy; abdominal pains in children beyond the age of infancy; bilious attacks, so called, in children; fever of obscure causation; jaundice in children; tuberculosis; rheumatism; some urinary disorders in childhood; mentally deficient children; head-nodding with nystagmus in infancy; and sleeplessness, loss of appetite, and some other symptoms. The various surgical measures in the treatment of hydrocephalus are gone into. In view of the increasing prevalence of poliomyelitis the author might have devoted some attention to the subject of the diagnosis of this disease during the prodromal stage. However, this is not a serious omission in a work of this kind, which treads only upon the firm ground of the author's own experience. The paper, typography and binding are in keeping with the high standards that have been maintained by the Oxford University Press. The book may be recommended without reserve as a valuable contribution to the already extensive literature of pediatrics.

Report from the Pathological Department and the Department of Clinical Psychiatry, Central Indiana Hospital for the Insane, 1909-1910 and 1910-1911. Vol. IV. Indianapolis: Wm. B. Burford, Contractor for State Printing and Binding, 1912.

The value of this report is attested in letters embodied from men connected with the colleges of Indiana. It is also evident that the opportunities for instruction afforded by the hospital to physicians and students availing themselves thereof are many and various. The report contains matter of interest to physicians of hospitals for the insane, to pathologists, and to specialists in nervous and mental diseases. It ought to encourage other hospitals to work along similar lines.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-eighth Annual Meeting, Held at Boston, Mass., May 30-June 1, 1912.

DR. E. W. TAYLOR, VICE-PRESIDENT, IN THE CHAIR.

Thursday, May 30—First Day.

Note on the Examination of the Cerebrospinal Fluid for Arsenic Following the Administration of Salvarsan.—Dr. CARL D. CAMP of Ann Arbor, presented this communication. The cerebrospinal fluid was withdrawn by lumbar puncture, following the administration of 0.6 gram of salvarsan by intravenous injection, and examined for arsenic in the laboratory of Dr. Victor C. Vaughan. The interval between the salvarsan injection and the lumbar puncture varied from 15 minutes to 40 hours in the seventeen observations that were made. Cases of tabes, paresis, cerebrospinal syphilis, secondary and tertiary syphilis not affecting the nervous system were utilized in this research. In only one case was there any trace of arsenic and in that case (3 hour interval) the patient was also being intensively treated with mercury and the trace was too small to make sure of its identity. Another case with the same interval showed no trace of arsenic. Arsenic does not appear in the cerebrospinal fluid as ordinarily administered, by intravenous injection, unless the dose is so large or so often repeated that there is danger of causing meningoencephalitis.

Dr. JOSEPH COLLINS of New York said that two years ago he began to treat cases of nervous syphilis with salvarsan and in that time had treated 137 cases. There had been cures, some of which had lasted eighteen months, which could not have been accomplished by anything else. Among these had been cases of brain syphilis, meningoencephalitis, vascular syphilis, tabes, syphilitic bulbar palsy, cases of syphilitic neurasthenia occurring in the wife or husband of patients who had had tabes or general paresis.

Dr. B. SACHS of New York said he had published one experience referring to eighty cases and since that time his experience had been doubled. He believed that no remedy that had ever been exhibited or employed in syphilis of the central nervous system had helped to such a degree as had salvarsan. He could not see that the presence or absence of arsenic in the cerebrospinal fluid would affect very much the question as to whether salvarsan ultimately benefits parasyphilitic or metasyphilitic changes in the nervous system. That it did bring about changes and affect the syphilitic virus as it circulated in the body there was no doubt. Both in private and hospital practice he had followed this matter closely and as a result he had never gone beyond 0.4 gram intravenously. This dose could be repeated after two or three or four weeks and it was much safer to give a small dose frequently repeated than to give a larger one.

Dr. DERCUM of Philadelphia said that in his experience the use of salvarsan in nervous syphilis depended upon the duration of the symptoms. The majority of paretics had not been benefited. As regarded tabetics he had seen no remarkable improvement. There had been cessation of tabetic pains and improvement in that way. One case was injected over a year ago by the intravenous method and pains were still absent. He always followed the salvarsan by mercurial inunctions just as vigorously as if salvarsan had not been used. One acted upon the germ and the other on the tissues. He believed that if the patient was not given both, he did not receive the maximum benefit.

Dr. KNAPP of Boston said that he could corroborate what Drs. Dercum and Sachs had said of salvarsan. He had not seen any disastrous results from it and certainly there could be no question of the beneficial effect.

Dr. CAMP said he had not intended to bring up any question of the efficiency of salvarsan in these cases. Of course it came up incidentally. If the effect of salvarsan was due to its antiseptic or germicidal effect, then arsenic or something which represented it should be present in the central nervous system. His experience as to the beneficial results had not been so favorable. The Argyll-Robertson pupils had not disappeared, there had been no return of the reflexes, though the patients had in many cases lost their subjective symptoms.

Clinical Confirmation of the Hypothesis That Disordered States in the Parents Produce Defective Offspring.—Drs. LUDLUM and CORSON WHITE of Philadelphia read this paper, stating that from an examination of 600 defective children they had concluded that changes in the chemico-physical environment of the developing ovum produced defective children. In all cases of arrested, retarded, or defective developments, all environmental factors should be most carefully eliminated before the especial defect should be stated as hereditary. Often, through defective nutrition or other untoward conditions of nurture, the organism was not able to perfect itself in all its parts, not from any germinal defect, but simply because it was not sufficiently nurtured, or because it was poisoned or otherwise injured as shown especially in children born during famine, in children of lead workers, etc. Statistics which exclude environment, as diseases or metabolic changes,etc., in the mother or father, are faulty, because, along with organic inheritance, ther must be a stimulus of an external developmental environment which supplies the stimulus without which hereditary potentials cannot be expressed. There was at least as much evidence for the retarding of the development of the ovum by untoward circumstances in the environment as there was for hereditary defect. The reason why statistics showed such a low percentage of syphilis or tuberculosis in defective children was because the majority of openly infected children died before their mental defect was definitely demonstrable and it was only those arising from parents with changed metabolism or low grade infection that persisted.

Dr. KNAPP of Boston said it was exceedingly rare to get an absolutely accurate history of the mother's condition during the period of pregnancy, but even without that it was often possible in those forms of disease, as those of more strictly degenerative character where heredity has been most often invoked, to obtain information as to the mother's condition during pregnancy which certainly must have a marked influence upon the development of the child. Such, for example, was an acute infection during the period of pregnancy which would certainly be explanatory of various degenerative conditions in later life.

An Examination of the Ductless Glands in Eight Cases of Dementia Præcox.—Drs. F. X. DERCUM and A. ELLIS of Philadelphia presented this paper in which they stated that their studies were prompted by the view that in dementia præcox we have to do with autointoxication. It was only relatively late in the disease that cases of dementia præcox showed quantitative mental loss, the striking early feature being confusion. In those cases the negative clinical history with regard to infections and intoxications from without, pointed to the conclusion that the toxins are produced within the body. That the ductless glands should be involved in this process of intoxication was extremely probable. That the glands of internal secretion were also closely interrelated to each other was another fact of prime importance. This relationship was no longer a matter of theory and of speculation but must be regarded as established. There was reason to believe that the organism in dementia præcox was one which unfolded or evolved imperfectly and irregularly and that at the time when adolescence takes place, the response on the part of the ductless glands was imperfect. During the last four years there had been studied clinically in the Insane Department of the Philadelphia General Hospital a large number of cases in reference to the ductless glands. Of these cases 8 came to autopsy. Cases 1, 3, and 5 suffered apparently from hebephrenia; 2 and 4 from catatonia, the 6th was catatonic at times, the 7th and 8th while classifiable with hebephrenia, were distinctly paranoid. All of these cases died of tuberculosis. In the cases of dementia præcox, the thyroid gland was studied in 8 cases, the hypophysis in 8, the adrenals in 8, the parathyroids in 5, the carotids in 6, the thymus in 1, and of the other glands, the testicles were studied in 1, the pancreas in 8, the spleen in 7, the liver in 8 and the kidneys in 8. One of the most notable points in the ductless gland findings was the underweight of the thyroid in 7 of the 8 cases. In addition 3 of them showed abnormalities in the colloid, quantitative or qualitative, and 4 decided regressive changes in the acinar epithelial cells. In the hypophyses there was less colloid than is usually found in a series of these glands. There was in all probability a disturbance in those cases of what Sajous has called the "adrenal system," *i. e.* of the chain made up of the pituitary, the thyroid and the adrenals. As far as the thyroid gland was concerned, the changes were to be explained in terms of inadequacy. Now Sajous has pointed out that in tuberculosis there was an inadequacy of the adrenal system and the thought naturally occurred that those eight patients suffered from dementia præcox for the same reason that they suffered from tuberculosis. It was rather a remarkable fact that the almost universal cause of death in dementia præcox was tuberculosis, and, if feebleness of resistance to the tubercle bacillus was due to the inadequacy of the adrenal system, there was reason to infer that this inadequacy pre-existed and that it was one of the factors in the makeup of dementia præcox.

Dr. Starr of New York said that about fifteen years ago he was exceedingly interested in the study of cases of cretinism and particularly of myxedema. It so happened that there came into his office within one week a case of myxedema in a young woman about eighteen and two cases that would now be classified as dementia præcox. The striking resemblance in the mental characteristics of the three individuals led him to regard the three cases as instances of maldevelopment, and to administer to them thyroid extract. The people were still under his observation. While there had not been a development of very great genius, yet these young women were perfectly able to live with their families, able to go about ordinary occupations and were fairly good members of society; whereas without that line of treatment they would long since have been confined to an asylum. On the basis of those cases he had put almost every case of dementia præcox that he had seen on thyroid treatment. In a good many of them it had done no good, but it had been of decided benefit in a certain number of cases and he was quite convinced with Dr. Dercum that treatment along that line with either the thyroid or pituitary gland, in a good many cases of dementia præcox was decidedly beneficial.

Dr. Onuf of New York said he had found on the whole that the manic-depressive form of insanity was quite responsive to thyroid treatment, as there was quite a distinct effect upon the psyche in the direction of elation. On the contrary, in the dementia præcox cases there was a peculiar irresponsiveness to the thyroid treatment.

Dr. McCarthy of Philadelphia said that in 500 autopsies at the Phipps Institute of patients dying with tuberculosis the thyroid was carefully examined and showed extensive lesions in a large percentage of cases. In this study of Dr. Dercum's, great caution should be used on account of these lesions.

Myasthenia Gravis.—Dr. M. Allen Starr of New York said he had gathered 250 cases of myasthenia gravis for purposes of analysis. Of these 142 were females and 108 males. The youngest case on record was 2 years and 9 months old, the oldest 72. The age of greatest frequency was between 20 and 30. It was true that the cranial nerves were chiefly affected. Thus ptosis or double vision had been recorded as the first symptom in 40 per cent. of cases. The difficulty in speech was more commonly due to paralysis of the tongue or lips. Difficulty in swallowing had been recorded in 8½ per cent. of the cases. A striking point of contrast between true bulbar palsy and myasthenia gravis was that diplopia and ptosis were present in the former and in true bulbar palsy double vision was very rare. The predominant symptom is weakness in the limbs; early fatigue on exertion and recovery of power on rest. Enlargement of the thymus gland had been observed in 28 per cent. Its absence in 72 per cent. seemed to show that it was not essential to the development of the disease. The pathology of the disease was obscure, but it had been shown that creatinin was diminished in the excretions in about 80 per cent. In the large majority of cases death occurred in six months. That the disease was an extremely serious one was shown by a large percentage of fatal terminations within a year of the onset. It was important to differentiate from diphtheritic paralysis and acute poliomyelitis of the acute bulbar type. The use of thyroid, pituitary and parathyroid gland seemed to have been very universal in the past ten years, but so far results of this treatment had not been successful. Strychnine and calcium lactate had been used in some cases with benefit.

Dr. Spiller of Philadelphia stated that cases of myasthenia gravis with recovery were sufficiently rare to make them worthy of record. Therefore he related the following: A middle-aged lawyer had marked symptoms. There were difficulty in swallowing fluids and ocular palsies. In dressing he would put on his trousers and find it a great effort to put on his coat and vest. He commenced his meal and after a few minutes would be unable to continue it. This was five years ago. He had a letter from him within the last two weeks. He had just returned from a journey of 2,000 miles and had been able to continue his cases in court with even more ability than before the disease occurred. Calcium lactate was no doubt of value in treatment. The speaker thought the avoidance of every form of fatigue, and the wearing of smoked glasses for the house and more deeply smoked ones for the street were essential in treatment.

Dr. Pearce Bailey of New York said the most characteristic manifestation of myasthenia gravis was its periodicity. Such collections as Dr. Starr has made were very timely, but at the same time, in view of the periodicity, he thought there was a danger in crowding together so many cases of giving myasthenia gravis a place which it did not deserve. There were so many varying types of the disease. He doubted whether anyone could distinguish between relapsing third nerve palsy and myasthenia gravis. Possibly myasthenia gravis was only a symptom-complex which came up in organic nervous disease and as a result of certain intoxications. If we could assume that the ductless glands were the basis of the disease, then the variation of the symptoms might be explained by whatever caused disturbance of their functions and the determination of the type by the particular biological alterations of the muscular system.

Dr. Mills of Philadelphia said he had seen quite a considerable number of cases of what he believed to be true myasthenia gravis and had published some of them. He had seen cases in which apparent recovery had lasted ten years or more. In his experience diseases, which had been supposed to be myasthenia gravis, had really been hysteria, disseminated sclerosis, forms of cerebrospinal syphilis and rarely cases of post-infectious paralysis and one or two cases of what were supposed to be poliomyelitis, or polioencephalitis inferior or superior. Treatment in his experience had been rest, with precautions, and the rather increasing use of nux vomica or strychnine.

Dr. George A. Waterman of Boston said that myasthenia gravis was not a disease of the nervous system. All its clinical phenomena pointed to toxemia. He pointed an analogy between myasthenia gravis and that other disease of the glands characterized by persistent thymus and tremendous over-development of lymphatic structures. There was a distinct analogy between lymphatism with sudden death and relaxation and palsy of muscles due to myasthenia gravis.

Dr. N. E. Brill of New York said it was worth while to give consideration to choking of the lymphatic spaces. In myasthenia gravis the condition of the muscle prevented rapid deterioration. This was closely related to what was found existing in normal fatigue. If the normal muscle was stimulated and the products of metabolism were prevented from being carried off, very quickly this state of fatigue set in, so that further contractions were impossible.

Dr. Starr, in concluding, protested against Dr. Bailey's supposition that the condition was one that might arise under any circumstance and that it did not present a typical assemblage of symptoms forming a disease. Dr. Starr maintained that there was a clinical syndrome that was perfectly characteristic and could not be mistaken for anything else.

Acute Bulbar Palsy Following in the Wake of Mumps; a Contribution to the Literature of Poliomyelitis.—Dr. Joseph Collins and Dr. Robert G. Armour of New York presented this paper which was based on a study of an 11-year old boy who complained eight days after the onset of a mild attack of mumps, of dizziness, headache, and malaise. The next day he staggered on attempting to walk and had partial paralysis of the left face. He developed rapidly dyspnea and died on the third day of the illness. Section through the oblongata, pons and crura showed a severe inflammatory round cell infiltration most pronounced at the superior level of the bodies diminishing in intensity in both directions from this level. The round cells appeared similar to those seen in poliomyelitis. There were a few cells resembling polyblasts. The greater number of cells were lymphocytes. The ganglion cells showed all stages of chromatolysis.

Dr. Israel Strauss of New York said that it appeared to him that Dr. Collins' case, interesting as it was, was simply a case of poliomyelitis coming on in an individual who happened to have had an infectious parotitis.

Dr. Sachs of New York said that without wishing to criticise the interpretation of the case at all, he thought it would be perfectly safe to speak of a case of that sort as a case of infectious polioencephalitis and leave the question as to whether it was really identical with a poliomyelitis unsettled for the present.

Dr. N. E. Brill of New York said that the parotid glands were peculiarly involved in general septic conditions and it was possible that the inflammation of the parotid glands was the beginning of a general infectious process secondary perhaps to a middle ear disease, inasmuch as Dr. Collins had stated that the tympanic cavity was filled with a serous effusion.

Dr. Collins said that he had never in 25 years' hospital experience encountered a case like that reported. It seemed to him extraordinary that a boy apparently well should feel a little dizzy on Wednesday and on Friday be dead; then to send specimens to skilled pathologists and have them say that they could not distinguish the lesions from poliomyelitis. Therefore, he ventured to say that it might be a contribution to the pathology of poliomyelitis.

Cerebellotegmental Lesion from Occlusion of Branches of the Superior Cerebellar Artery.—Dr.

Charles K. Mills of Philadelphia read this paper which embodied investigations into the literature of the organic basis of emotional expression, a study of the functions of certain tegmental tracts, histological investigations by means of serial sections and a study of the distribution of the superior and posterior inferior cerebellar arteries. The microscopical investigation was made by Dr. W. G. Spiller and the study of arterial distribution by Drs. Ludlum and E. M. Williams. Dr. Mills' conclusions were mainly based upon his study of the literature of the subject and on the complete investigation of the particular case which formed the basis of the article. Other unreported cases were included. The persisting symptom-complex in this case for four years from the time of the original attack until the death of the patient was ataxia in the left upper and the left lower extremity, complete right-sided deafness, loss of the senses of pain, extreme heat and extreme cold and impaired tactile discrimination, on the right half of the body, with preservation on both sides of light touch and the senses of deep pressure and of position, passive movement and stereognosis; the retention, everywhere, of voluntary movement and complete paralysis of emotional expression on the right side of the face. The brain on close inspection by the naked eye showed a marked depression in the cerebellum above the dentatum, and this body as well as the tissues above it were much atrophied. The vessels on the upper surface of the left cerebellar lobe were much smaller than on the right. Many of the branches of the superior cerebellar artery were occluded. These occlusions were especially those of the branches of the ventral part of the corpus dentatum and the adjacent part of the superior cerebellar peduncle. The cerebellar nuclei in the neighborhood of the left corpus dentatum were equally affected. At least the upper two-thirds of the left superior cerebellar peduncle was degenerated, as a consequence of which the right nuclear ruber was at least one-third smaller than the left, but it apparently contained a full number of the nerve cells. The left mesencephalic root of the fifth nerve and the left lateral lemniscus were much degenerated. The whole process was evidently syphilitic as shown by much round cell infiltration in the pia. As the result of the study of the supply of the anterior superior and the posterior inferior cerebellar arteries it was found that the anterior superior supplies a considerable portion of the border of the pons and middle peduncle and the anterior lateral portion of the cerebellar cortex. The infiltration from stain extended into and included a portion of the superior cerebellar peduncle on its way from the dentate nucleus, and the anterior lateral portion of the dentatum itself. The black stain of the inferior cerebellar artery infiltrated an area of considerably less size. This included about the posterior one-third of the cortex of the cerebellar lobe and the vermis, and the posterior and posteromedian portions of the dentate nucleus. In addition to the above supplies, many minute black points or dots were found throughout the lateral tegmentum in the most caudal portion of the pons, showing the possibility that this artery in addition to its supply to the oblongata also reaches forward to some of the pontine tracts in the region of the medium lemniscus. More lateral to this the supply seemed to be that of the anterior superior. After reviewing the hypothesis of von Bechterew, Lewandowsky, and others, Dr. Mills submitted his own views of the interior mechanism of emotional expression. These included the predication of an emotional motor zone, especially developed in the right frontal lobe, anterior to the precentral convolution, this being connected by way of the internal capsule and lenticular nucleus with the nucleus ruber and the ventral pontile nuclei, the afferent portion of the mechanism being by way of the dorsal pontile nuclei, special tracts in the tegmentum to the thalamus, tracts from the thalamus to the parietal lobe and thence to the frontal emotive zone, reenforcement taking place for coordination and muscular tone from the cerebellum by way of the superior cerebellar peduncle. The histological study of the chief case of the paper affords some new light upon the afferent lemniscal tracts.

Dr. James J. Putnam of Boston said he had recently seen in consultation a case very much like the one reported. This condition was sufficiently rare to make it valuable to collect such cases. He had seen only two similar cases.

Dr. Theodore Diller of Pittsburg said that he would like to refresh Dr. Mills' memory in regard to a girl about 14 years of age, whom Dr. Mills and he examined two years ago. She had symptoms indicative of a brain tumor and had one symptom which was especially marked, that was a very distinct hemiataxia. An operation was done over the cerebellum on the side which seemed to be implicated and nothing was found, but the death of the patient some little time later showed a tumor of considerable size almost in the region which Dr. Mills has indicated as present in his case, namely, involving the dentate nucleus and superior peduncles. The red nucleus seemed to be entirely intact.

Tabes Dorsalis: The Exhaustion Theory of Its Pathogenesis with Experimental Evidence.—Dr. Colin K. Russel of Montreal presented this communication in which he stated that the pathogenesis of tabes dorsalis was admittedly unsatisfactory. In tabes there was probably a slowly acting toxin which influenced cell metabolism in a deleterious manner so that the building up process was relatively insufficient and the cells became exhausted. The cells which were most constantly active, and which we would expect to be affected first, were those cells which maintained the tone and position of the muscles, especially those muscles which were most frequently called into activity. The distal parts of the neurone underwent atrophy and thus the peculiar anatomico-pathological condition of the fibers in the posterior columns might be accounted for. The practical absence of any lesion in the posterior ganglia was also explicable. The reaction of the pupils to light, being far more frequent and active than that to accommodation, produced an exhaustion of the neurones subserving that function, giving rise to the well-known Argyll-Robertson pupil. Clinically this theory explained also the fact that men were more frequently affected than women and why the natives of tropical countries were practically immune to the disease. The lightning and girdle pains were probably due to a definite syphilitic process in the spinal meninges as was shown among other things by their alleviation after salvarsan treatment. Following up this theory the writer had been able to produce the Argyll-Robertson pupil in rabbits which had first been inoculated with the *Treponema pallidum*, by subjecting them to alternating light and darkness, by means of a miniature revolving lighthouse. Control rabbits which had not been inoculated did not develop any abnormality of the pupil although placed under the same conditions, and rabbits which had been inoculated but had not been subjected to the light stimulation also remained normal.

Dr. Sachs of New York said he had tried ever since Edinger first formulated his theory to reconcile the facts with the theories or the theories with the facts, but could not say that he had adopted the theory as anything more than an interesting theory. It had not proved particularly helpful in the explanation of the morbid processes. It seemed easy enough to explain a number of the morbid symptoms on the basis of the theory, but, on the other hand, there were a number of cases that we all see in which just the opposite course occurs to what one would expect if the theory were true.

Dr. Collins of New York said he was in a position today to say that a case had come under his observation in which the Argyll-Robertson pupil existed according to the opinion of three competent trained neurologists and that it disappeared after active salvarsan therapy. If Dr. Russel's very ingenious explanation, or rather his explanation of the Argyll-Robertson pupil based on this ingenious experiment which he had carried out, was true, and Dr. Collins saw no reason why it should not be considered to be so, then it was likely that that and the other cardinal symptoms of the disease might be relieved if attacked sufficiently early by appropriate therapy. These observations support the contention that tabes is in reality a meningitis which is an expression of a syphilitic infection.

Dr. Hugh T. Patrick of Chicago said he had not been able to find facts in his practice to support Edinger's theory. On the contrary, he had been inclined to think that such patients as pursued an occupation making a particularly strong call upon one set of extremities were apt to suffer on that side less. He narrated the case of a painter of pictures who was and always had been very sluggish in regard to general exercise, who became rapidly exceedingly ataxic in his legs, but painted his pictures extraordinarily well.

Dr. F. W. Langdon of Cincinnati said that Dr. Russel had given an extremely valuable contribution to what might be termed the rational pathology of tabes. Some 15 years ago in a paper upon the subject Dr. Langdon alluded quite emphatically to the biological reason for the preponderance of tabes in the lower extremities in man. Man had for a comparatively few generations been walking on his hind legs, so to speak, and those were the neurones that had no rest. The muscle sense was continually acting even in the sitting position and more so in standing. Some years later, when Edinger's exhaustion theory was promulgated, Dr. Langdon called attention to not only the upright position as causing this constant strain, but also the enormous demand on the sensory light reflex of the pupil.

Dr. Russel, in closing, said he had found a great many patients who had not done well on the Fraenkel treatment,

In those cases it had practically always turned out that in their enthusiasm to get well they had overstepped the limit and done too much and they had exhausted themselves rather than reeducated themselves. The only way to prevent this was to take the pulse as an indication as to when the patient was becoming exhausted. In every case that he had experience with where this had been done the patients had become reeducated.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held at the Barnard Free Skin and Cancer Hospital, St. Louis, Missouri, May 23, 24, and 25, 1912.

THE PRESIDENT, DR. GROVER W. WENDE OF BUFFALO, IN THE CHAIR.

President's Address.—This consisted of a brief review of the history of American medical journalism in the field of dermatology.

A Critical Study of the Organisms Cultivated from the Lesions of Human Leprosy, with a Consideration of Their Etiological Significance.—Dr. CHARLES W. DUVAL of New Orleans, by invitation, presented a paper on this subject, which embraced a critical review of the acid-fast organisms that had been cultivated from the lesions of human leprosy in various parts of the world, together with an efficient cultural method which might be of distinct value in the early diagnosis of leprosy. The following conclusions were offered: 1. From a bacteriological study of 29 cases of leprosy, they had cultivated an acid-fast bacillus from 22 of these cases. 2. A chromogenic strain similar in all essentials to that described by Clegg was recovered from fourteen cases. 3. Under certain conditions the Clegg culture grew as (*a*) non-acid-fast streptothrix; (*b*) non-acid-fast diphtheroid; and, (*c*) an acid-fast bacillus. 4. Eight cases yielded an organism which thus far was distinctly different from Clegg's bacillus in its biological character, growing only upon special media and not producing pigment. 5. Animal experiments undertaken for the purpose of differentiating the two types recovered from the human leprous lesion and to fix their etiological status were not regarded by the author as conclusive. 6. Serological tests, especially those performed with highly immune sera, suggested that the leprosy bacillus of Clegg was not related to the non-chromogenic slow-growing culture from leprosy. 7. The rôle played by the chromogenic bacillus of Clegg in the production of leprosy was as yet an unsettled question. 8. The non-chromogenic strain, while behaving according to most of our notions regarding a pathogenic organism, had likewise not up to the present been proven to be the cause of leprosy, although he was impressed with the probability of such a rôle being eventually attributed to it, and he considered that it deserved more serious attention than any strain so far cultivated from the human leprous lesion. 9. The wide variation in morphology and staining reaction for certain cultures which subsequently became rapid growers and chromogenic explained the interpretations of European writers that the *Bacillus leprœ* was a bacterium of such pleomorphism that it could be recognized as a diphtheroid, a streptothrix, and an acid-fast bacillus.

Dr. ANDREW P. BIDDLE of Detroit referred to two cases of leprosy that had recently come under his observation in Michigan, and he stated that the occurrence of these sporadic cases in localities where leprosy was rarely found emphasized the importance of anything that threw more light upon the early diagnosis of the disease.

Experience with Noguchi's Luetin Reaction.—Dr. HOWARD FOX of New York said the successful cultivation of the *Spirochæta pallida* by Noguchi had opened up new opportunities for the experimental investigation of syphilis. A direct result of this achievement was the luetin reaction, a diagnostic cutaneous test similar to that of von Pirquet for tuberculosis. The reaction was produced by the injection of a suspension of the *Spirochæta pallida* that had been grown in pure culture and then destroyed by heat. In his experience with luetin, the speaker said he had followed the technique described by Noguchi in his original communication (*Jour. Exper. Med.*, XIV, 1911.) His experience with luetin was limited to 100 cases, 49 of which were cases of acquired syphilis, while the others were used as control cases and were suffering from various non-specific diseases of the skin. In fourteen cases of active secondary syphilis, the luetin reaction was positive in six cases, or 43 per cent.; the Wassermann reaction was positive in 100 per cent. of the cases. In 33 cases of tertiary and latent syphilis the luetin reaction was positive in seventeen, or 51 per cent.; negative in fourteen, and doubtful in two. The Wassermann reaction showed varying degrees of positiveness in nineteen, or 65 per cent., and was negative in ten. In four it was not performed. Most of the patients in whom a positive reaction occurred had continued up to the present time to show a bluish macule or tiny keloid at the point of the injection. Dr. Fox said that before an opinion of real value could be expressed upon the luetin reaction it would be necessary to study the results of a very large number of clinical investigations. His own experience was too small for definite conclusions to be drawn therefrom. It was, however, his hope and belief that the luetin test would prove to be of some value as a diagnostic aid, particularly in cases where the Wassermann reaction failed to give any definite information.

Erythema ab Igne.—Dr. M. B. HARTZELL of Philadelphia said that although most English and American treatises on diseases of the skin mentioned briefly the reticulate erythema and pigmentation which might follow the long-continued application of heat to the skin, very little was to be found about this curious and rather interesting affection in dermatological literature. French and German authors of recent treatises on diseases of the skin did not mention it at all. Indeed, the English dermatologists were apparently the only ones who saw it with any degree of frequency, and they were, consequently, the only ones who seemed to have a real practical acquaintance with it. While the malady was found principally in those who had exposed the skin to the heat of the stove or furnace, and in consequence was usually situated on the legs, it might follow exposure to other sources of heat and might be found in other situations. In one of the four cases reported by Dr. Hartzell the disease was situated in the lumbar and sacral regions, and had followed the long-continued application of a hot water bag. It was worthy of note that in all four of the cases here reported the patients were decidedly below the normal standard of health, either as the result of previous illness, alcoholism, or old age, and this seemed to be true generally. Indeed, he doubted very much whether the disease could occur in an ordinarily healthy individual. Although the inflammation rarely passed beyond the erythematous stage it might go on to decided thickening and even vesiculation. The result of the pathological examinations showed very clearly that the affection was an inflammatory one and not simply a staining of the skin, as had been claimed.

The Single-Dose X-Ray Method.—Dr. GEORGE M. MACKEE and Dr. JOHN REMER of New York presented a paper on this subject. The authors stated that the term single-dose *x*-ray method did not mean that the maximum amount of benefit must necessarily follow a single application. It was intended to signify a radical departure from the former fractional-dose method where small and repeated applications were made until the desired result was obtained. This often necessitated from fifteen to a hundred or more exposures in the treatment of a small rodent ulcer. With the single-dose method, on the other hand, from one to four treatments might be required in the treatment of a given lesion. Furthermore, a definite attempt was made to measure the amount of *x*-ray administered, so that the method was scientific and was associated with a certain degree of accuracy. Roughly speaking, there were two methods of administering the massive or single *x*-ray dose; one in which the quality of the rays was ascertained by the use of instruments, while the quantity was estimated by the duration of the exposure, the amount of current employed, and the distance of the tube from the lesion; the second method consisted of employing the usual qualitative instruments, with the addition of estimating the quantity by the use of pastilles composed of platino-cyanide of barium. Although both methods were difficult, and neither could be said to be absolutely accurate, the first was certainly the more unreliable and was associated with more troublesome and perplexing details. After describing the technique of both of these methods the authors passed on to the advantages of the single-dose method, by which it was now possible to obtain a defluvium of the entire scalp in from sixteen to twenty-five minutes. The entire surface of the body, if necessary, could be given a normal dose in a very short time. This possibility, however, could not be made use of in diseases such as mycosis fungoides, for fear of causing toxic symptoms. In this condition, where there were many lesions, it was only necessary to expose each lesion once, the treatments being given once or twice a week. Sycosis would usually heal under the influence of a single epilating dose. In epithelioma, under the old fractional-dose method, the tumor or ulcer would

often improve for a while and then continue to grow worse in spite of additional treatment. This did not appear to be the case since the advent of the single-dose method. By this method better results were obtained in many of the cutaneous diseases amenable to *x*-ray treatment, but it was not successful, so far as the authors were aware, in curing cutaneous affections that were not benefited by the older method. The technique of the single-dose method was difficult and exacting, and the novice was advised to become thoroughly acquainted with it through experimental work before employing it in practice.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEVADA STATE BOARD OF MEDICAL EXAMINERS.

May 6, 7, and 8, 1912.

ANATOMY.

1-2. Give location of the coronary sinus and its length. What valve guards its termination?

3. Describe the circle of Willis.

4. Give origin, insertion, and action of the rectus capitis anticus major muscle.

5. What organs are supplied with blood from the celiac artery?

6. What is a synarthrodial joint? Give an example.

7. Give location of the capsules of Bowman.

8-9. Give description and location of Cowper's glands. What glands in the female correspond with Cowper's in the male?

10. Name the nerves that supply the tongue with taste, sensation, and motion.

PHYSIOLOGY.

1. What inorganic salts does muscular tissue contain?

2. What is the specific gravity of human blood? (*a*) What is the relative weight of the blood to the body?

3. What functions have the leucocytes?

4. What are enzymes?

5. What is lymph?

6. What part does the liver play in the general nutrition of the body.

7. What is the origin and significance of urea? (*a*) Normally, what per cent. does urine contain? (*b*) What quantity is eliminated in twenty-four hours by the healthy adult?

MATERIA MEDICA AND THERAPEUTICS.

1. Write a complete prescription for a cathartic pill—not official—containing at least three active ingredients.

2. Define a mixture, a sinapism, a lotion, a liniment.

3. Give the habitat of ipecacuanha, coca erythroxylon, cascara sagrada, strophanthus.

4. Describe the physical properties of tr. ferri chloridi, acidum salicylicum, liquor plumbi subacetatis.

5. Write a prescription for a diarrhea mixture containing at least three drugs.

6. Name three remedies you might use in a case of typhoid fever. Give reasons.

7. Differentiate the physiological action of opium from chloral hydrate.

8. In heart conditions, when would you use nitroglycerin, strychnine, strophanthus, digitalis?

9. Give proportionate dose for child of two weeks, one year, and adult. Give exceptions.

10. Give a classification of cathartics, with example of each.

CHEMISTRY AND TOXICOLOGY.

1. Write the chemical formulæ to represent the reaction that takes place in boiling Fehling's solution with diabetic urine.

2. Write three prescriptions in which a chemical change takes place. Give results.

3. Give the chemical name for Epsom salt, Rochelle salt, tartar emetic, copperas, blue vitriol.

4. Describe a method for detecting arsenic.

5. How would you prepare an antidote for arsenic?

6. Differentiate acute alcoholism from concussion of the brain.

7. Give the symptoms and treatment of a case of cannabis indica poisoning.

8. What is the cumulative effect of digitalis?

9. Give symptoms and treatment of a case of attempted suicide by a mineral poison.

10. Give symptoms and treatment of a case of attempted suicide with a vegetable poison.

BACTERIOLOGY.

1. Describe in full one method of staining for bacteria.

2. Describe the *Diplococcus lanceolatus* of Fraenkel and the method of staining for it.

3. Differentiate between the *Micrococcus catarrhalis* and the *Micrococcus intracellularis meningitidis?*

4. Define epidemic, endemic, pandemic, bacillus, toxins, alexin, faculative anaërobic?

5. Describe the *Streptococcus erysipelatis?*

6. Differentiate bacteriologically between diphtheria and tonsillitis.

7. Describe the spirochete of Vincent's angina.

8. How would you determine the presence of pathogenic bacteria in milk?

9. Given a specimen of sputum, how would you determine whether the tubercle bacillus was present or not?

10. If you were a health officer what means would you take to prevent the spread of a contagious disease?

PATHOLOGY.

1. Differentiate between carcinoma and sarcoma.

2. Give in detail the pathology of the first stage of lobar pneumonia.

3. Give the lesions occurring in a case of amebic dysentery.

4. Describe the pathological changes that occur in hypertrophic cirrhosis of the liver.

5. Give the microscopical appearance of the blood in progressive pernicious anemia.

6. Give the pathology of chronic parenchymatous nephritis.

7. What do you mean by the term "malignant growth"? Give examples.

8. Give the pathology of acute interstitial myocarditis.

9. Give the pathology of amyotrophic lateral sclerosis.

10. Describe the two chief degenerative changes in a tubercle.

PRACTICE OF MEDICINE.

1. How does dysentery differ from ordinary diarrhea?

2. Differentiate empyema and pleurisy with effusion.

3. What are the physical signs of aortic regurgitation?

4. Outline the area of normal liver dullness.

5. What are the causes of endocarditis?

6. How do human beings acquire tapeworm?

7. Mention the causes and symptoms of gastralgia.

8. Give the physical signs of a cavity of the lung in pulmonary tuberculosis.

9. What is bronchorrhea?

10. Why does ascites occur as a consequence of cirrhosis of the liver?

OBSTETRICS.

1. Give pathological anatomy of a vesicular mole.

2. Give etiology and diagnosis of rachitic pelvis.

3. What effect has placental syphilis upon the fetus?

4. Give cause of intrauterine amputations.

5. From what month does the placenta date?

6. What is the principal cause of eclampsia?

7. What position does the uterus assume during the first three months of pregnancy?

8. What are the most grave gynecological diseases to anticipate after delivery?

9. Describe an operation for tubal pregnancy.

10. Give clinical history of ruptured uterus.

SURGERY.

1. What are the symptoms of air embolism? (*a*) Give treatment. (*b*) Surgical operations in what regions are most liable to be followed by this accident?

2. What is the first surgical principle in the treatment of infected wounds? (*a*) Give in minutiæ your treatment of infected wounds.

3. Give treatment of rattlesnake bite.

4. Reduce a dislocation at the elbow, both bones of the forearm backward. (*a*) Give after treatment.

5. Give technique of operation for appendicitis.

6. What is Pott's disease? (*a*) How would you treat this condition?

7. Describe burns of the first, second, and third degrees. (*a*) Give treatment.

8. For the cure of what disease is neurectomy employed? (*a*) In what cases may success be expected. (*b*) Give technique of operation.

9. What are the symptoms of complete and partial injury of the spinal cord?

10. Give treatment of lymphangitis.

GENITOURINARY AND DERMATOLOGY.

1. How would you treat a case of urethral chill?

2. What are the symptoms and treatment of gonorrheal rheumatism?

3. Give symptoms of stone in the bladder.

4. What are the symptoms and treatment of acute prostatitis?

5. How would you treat a case of chronic posterior urethritis?

6. What are the causes, symptoms, and treatment of verruca?

7. Describe seborrhea.

8. What is hypertrichosis?

9. What are the causes, symptoms, and treatment of vitiligo?

10. Give the diagnosis and treatment of an epithelioma.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEVADA STATE BOARD OF MEDICAL EXAMINERS.

May 6, 7, and 8, 1912.

ANATOMY.

1 and 2. The *coronary sinus* is situated in the posterior part of the left auriculoventricular groove. It is about one inch in length. Its termination is guarded by the Thebesian valve.

3. The *circle of Willis* is situated at the base of the brain. It is formed in front by the anterior cerebral arteries, which are connected by the anterior communicating artery; behind by the two posterior cerebral arteries, which are connected on each side with the internal carotid by the posterior communicating arteries.

4. The *rectus capitis anticus major* muscle arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ; is inserted into the basilar process of the occipital bone. It draws the head forward after it has been drawn backward; it also serves to flex the head and to rotate it.

5. The *celiac artery* supplies the stomach, lower end of esophagus, lesser omentum, liver, gall-bladder, pancreas, and spleen.

6. A *synarthrodial joint* is one in which there is no motion; the bones are in almost direct contact, and there is no joint cavity. *Example:* The articulation between the occipital and the sphenoid bones.

7. *Bowman's capsule* surrounds the glomerulus of the kidney.

8 and 9. *Cowper's glands* are two small rounded bodies behind the membranous portion of the urethra, between the two layers of the triangular ligament. In the female the glands of Bartholin correspond to Cowper's glands in the male.

10. The *tongue* is supplied with *taste* by the chorda tympani and glossopharyngeal; with *sensation* by the inferior maxillary and glossopharyngeal; and with *motion* by the hypoglossal nerve.

PHYSIOLOGY.

1. The *inorganic salts in muscular tissue* are: Chlorides, sulphates, and phosphates of sodium, potassium, calcium, magnesium, and iron; chiefly potassium phosphate.

2. The specific gravity of human blood is about 1055 to 1065. The relative weight of blood to the body is about 1:13.

3. *Function of the leucocytes:* (1) To serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

4. An *enzyme* is a body produced by a living organism, or cell, and is capable of effecting certain chemical changes without itself undergoing change in the process.

5. *Lymph* is an alkaline fluid derived from the blood and found in the lymphatic vessels, in the thoracic duct, and in the large lymphatic trunks.

6. The *functions of the liver* are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat; (5) the conversion of poisonous and harmful substances into inert material.

7. *Urea* is one of the most important of the end products of proteid metabolism. It is the main form of the nitrogen eliminated. The urine normally contains about 2 per cent. of urea, and a healthy adult eliminates about 500 grains of urea in twenty-four hours.

MATERIA MEDICA AND THERAPEUTICS.

1. ℞ Scammonii]
Jalapæ } āā gr. ij.
Saponis]
Tinct. zingiberis q.s. M.
Fiat pilula.

2. A *mixture* is an aqueous preparation which contains insoluble substances in suspension. It is intended for internal use.

A *sinapism* is a mustard plaster.

A *lotion* is similar to a mixture, but is for external use.

A *liniment* is a preparation consisting of a solution of some medicament in alcohol or oil or water, and is applied by friction to the skin.

3. The *habitat* of ipecacuanha is Brazil to Bolivia; of coca erythroxylon, Peru and Bolivia; of cascara sagrada, Idaho and westward; of strophanthus, tropical Africa.

4. *Tinctura ferri chloridi* is a bright brownish liquid having a slightly ethereal odor, an astringent taste, and an acid reaction.

Acidum salicylicum is a white crystalline powder, or prismatic needles, odorless, of a sweetish taste which becomes acrid, not very soluble in water, but very soluble in boiling alcohol.

Liquor plumbi subacetatis is a clear, colorless liquid with a sweetish, astringent taste and an alkaline reaction.

5. ℞ Tincturæ opii]
Tincturæ capsici |
Tincturæ rhei } āā 5j. M.
Spiritus camphoræ |
Spiritus menthæ piperitæ]
Sig.: Thirty minims in water.

6. Cold water, to reduce the temperature; turpentine, for tympanites; opium, for hemorrhage from the bowels.

7. *Chloral* is of no use if there is pain; it lowers the body temperature, and has no effect on the pupil.

Opium relieves pain, makes the skin warm, and causes itching; and contracts the pupil.

8. Digitalis is indicated in diseases of the heart: (1) when heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high.

Strophanthus is used as a cardiac stimulant; in mitral or aortic obstruction; in cardiac dilatation; palpitation; alcoholism; exophthalmic goiter; nephritis; when heart action is feeble but rapid, and accompanied by low arterial tension; in general, same as digitalis.

As compared with digitalis, strophanthus acts quicker, is less enduring in its effects, is less certain, is not cumulative, has less marked vasoconstrictor effects, has greater diurectic power, and is said to be safer for aged patients.

Nitroglycerin causes a dilatation of the blood-vessels, fullness in the head, giddiness, buzzing in the ear, the heart beat increases in rate and force, arterial tension decreases, it is a cardiac and nerve depressant, respiration is first stimulated and then depressed, it produces frontal headache. It is *indicated* in angina pectoris, cardiac dyspnea, chronic nephritis, with high tension pulse, vomiting, epilepsy, hiccough, asthma.

Strychnine is used as a vasoconstrictor to raise the blood pressure, and as a cardiac stimulant.

9. "Infants under a year receive 1/20 of the adult dose; and at the age of one year 1/10 of the adult dose is safe." —(Koplik.)

Children are very susceptible to opium, so that drug should be given in smaller doses; arsenic and belladonna are well borne, so they may be given in larger doses.

10. *Cathartics* may be classified as: Laxatives (manna); Purgatives (rhubarb); Drastic (croton oil); Hydragogue (magnesium sulphate); Cholagogue (mercury).

CHEMISTRY AND TOXICOLOGY.

1. When the two parts of Fehling's solution are mixed the following reaction occurs:

$$CuSO_4 + 2KOH = Cu(OH)_2 + K_2SO_4.$$

If glucose is present in the added urine oxygen is taken out and cuprous oxide is formed:

$$2Cu(OH)_2 = 2H_2O + O + Cu_2O.$$

2. *Three examples of chemical incompatibility:*

(1) ℞ Sodii boratis, gr. x.
Zinci sulphatis, gr. j.
Aquæ camphoræ, f5j.
Aquæ rosæ, q.s. ad f5j.
Misce.
Sig.: One drop in each eye night and morning.
The zinc is precipitated by the borax as zinc borate.

(2) ℞ Antipyrinæ, gr. xx.
Hydrargyri chloridi mitis, gr. x.
Sodii bicarbonatis, 5j.
Misce et fiant chartulæ No xx.
Sig.: One every three hours.

In the presence of moisture this mixture turns gray, due to the formation of metallic mercury and mercurous oxide. Mercuric chloride is also formed.

(3) ℞. Quininæ sulphatis, gr. xx.
Potassii acetatis, gr. xl.
Acidi sulphurici aromatici, ɱxviii.
Aquæ cinnamomi, q.s. ad f℥ij.
Misce.
Sig.: One teaspoonful after meals.

In this prescription a voluminous precipitate of quinine acetate is formed which cannot be poured from the bottle.—(Thornton's *Materia Medica.*)

3. Epsom salt is magnesium sulphate; Rochelle salt is potassium and sodium tartrate; tartar emetic is antimonyl potassium tartrate; copperas is ferrous sulphate; blue vitriol is copper sulphate.

4. *Test for arsenic:* Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

5. To prepare an antidote for arsenic keep the two following solutions in separate bottles and when needed mix them and administer:

℞. Liq. ferri tersulphatis, ℥ij.
Aquæ, ℥vj. M.
℞. Magnesiæ, ℥iij.
Aquæ, ℥viij. M.

6.

ACUTE ALCOHOLISM.	CONCUSSION OF BRAIN.
Can be aroused by supra-orbital pressure unless very profound.	Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.
Pupils normal or somewhat dilated.	Pupil dilated on side of lesion. Choked disc.
Pulse more rapid than normal and full.	Pulse very slow.
Regular respiration.	Respiration slow and stertorous.
Temperature may be low or normal.	Temperature higher—101°.
Urine normal.	Urine normal or contains trace of albumin.
No hemiplegia.	Hemiplegia on opposite side to that of injury. If contusion of brain is also present may have generalized convulsions.

7. Dilated pupils, coma, lowered reflexes, vertigo, headache, anesthesia of skin, and ravenous appetite. *Treatment:* Emetics, alcohol, strychnine, and lemon-juice.

8. Cumulative effect of digitalis is: Irregularity of the heart, dicrotic pulse, headache, and vomiting.

9. The *symptoms of acute lead poisoning* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms."

The antidotal treatment consists in administering "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube."

10. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

Treatment: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible."—(Witthaus' *Essentials of Chemistry.*)

BACTERIOLOGY.

1. *Gram's method of staining:* Stain a cover glass preparation for two or three minutes in anilin gentian-violet. Wash in water. Treat with Gram's solution (iodine, 1 gram; potassium iodide, 2 grams; water, 300 c.c.) for a minute and a half, when the preparation becomes nearly black. Decolorize with strong or absolute alcohol for at least five minutes, wash, dry, and mount. Sometimes a contrast stain of Bismarck brown or eosin is used.

2. *The diplococcus lanceolatus of Fraenkel* is non-motile, non-flagellate, non-sporogenous, non-chromogenic, non-liquefying diplococcus; it is aërobic and optionally anaërobic. It stains by the ordinary methods, also by Gram's method. (See QUESTION 1.)

3. The *micrococcus catarrhalis* is a coccus; the *micrococcus intracellularis meningitidis* is a diplococcus.

4. *Epidemic* implies a disease attacking a large number of people in a community nearly simultaneously.

Endemic implies that a disease is always more or less present in a community.

Pandemic is a disease that is epidemic over a very wide area.

Bacillus is a rod-shaped bacterium.

Toxins are the poisonous products of bacteria.

Alexin is a defensive body existing normally in the blood serum.

Facultative anaërobic implies that a bacterium can live and thrive either in the presence of oxygen or without oxygen.

5. The *Streptococcus erysipelatis* appears in chains of varying lengths or in tangled masses, the presence or absence of oxygen does not seem to be of much importance, it grows at room temperature, and has the cultural characteristics of the *Streptococcus pyogenes.* This latter is a micrococcus, of spherical shape, and arranged in chains of about thirty or forty cocci (in liquid media), but the chains are much shorter in solid media. Each coccus is about one-half to two mikrons in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method. It grows very well on blood serum and milk, also on gelatin, and agar.

6. The *Bacillus diphtheriæ* (of Klebs-Loeffler) is present in diphtheria and is not present in tonsillitis.

7. *The spirochete of Vincent's angina* is a long, slender, anaërobic bacillus, with pointed ends, slightly swollen in the middle, it is non-motile, and does not stain by Gram's method.

8. *To determine the presence of bacteria in milk:* "As a routine procedure, in cold weather, entirely satisfactory results may be obtained by taking 1 c.c. of the milk to be examined, after it is thoroughly mixed, and putting it into 9 c.c. of sterile water, and taking 1 c.c. of this solution in 9 c.c. of sterile water. Plates made from this dilution with 1/10 c.c. and with 1 c.c. respectively have been found to give closely corresponding results, and unless the milk is badly contaminated it is always possible to count the colonies readily. In warm weather and in the case of cream a third or even a fourth dilution should be made. Where the milk or cream are mixed with the medium in the tube the resulting colonies are apt to be more uniformly distributed on the plate than where the milk is put into the Petri dish and the culture medium poured in afterward. The number of bacteria remaining in the test tube in the former method of procedure must be very few where the medium is properly fluid when it is poured."—(Williams' *Bacteriology.*)

9. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length, and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, and nonchromogenic, is aërobic; it resists acids; it grows well on blood serum; stains well by Ehrlich's, Ziehl-Nielsen's, or Gabbett's method; it is Gram-positive.

10. All infectious and contagious diseases should be promptly reported and proper isolation or quarantine be insisted on. One of the chief things is to watch the schools; here there should be regular and efficient inspection by physicians; prompt exclusion and isolation of any one suffering from a contagious disease, or coming from a house where such disease is; compulsory vaccination; compulsory notification of all infectious and contagious disease; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease, or who have come from a house where such disease prevailed, should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

PATHOLOGY.

1. *Carcinoma* is apt to occur at a later age; is found in structures derived from the epiblast or hypoblast; possesses a fibrous stroma, in which are found both blood-vessels and lymphatics; metastasis is by the lymphatics.

Sarcoma is apt to occur earlier; is found in structures derived from the mesoblast; there is no stroma between the cells; the blood-vessels are in direct contact with the tumor cells; there are no lymphatics; metastasis is by the blood-vessels.

2. *Stage of hyperemia*, or congestion, consists in distention of the vessel of the alveoli encroaching on the cavity of the air-vesicle; the lung has a reddish-brown color, is more resistant, and is heavier, sinking somewhat lower in water than a normal lung, and having a slight exudation upon the vesicular surface. The same changes are seen in the adjacent bronchioles.

3. In *amebic dysentery* there are pronounced ulcerations in the intestines (chiefly the colon); abscess of the liver is frequent; and occasionally there is perforation into the right lung. The inflammatory process is severe, the exposed follicles necrose, the sloughs separate, and thus the ulcer is formed. The ulcer has irregular and undermined edges, and when it heals there is marked cicatrization.

4. In *hypertrophic cirrhosis of the liver:* The liver is large, yellowish, the interlobular connective tissue is proliferated and extends into the peripheral zones of the acini and between the hepatic cells; proliferation of the liver cells and bile ducts may also be found.

5. In *progressive pernicious anemia:* The marked feature of the disease is pronounced oligocythemia. This progresses rapidly, and in ordinary cases the number of red corpuscles sinks to 1,000,000 or less per cu. mm.; at the same time, changes in size (microcytes and megalocytes) and in shape (poikilocytes) make their appearance and reach grades rarely attained in other diseases. Nucleated red corpuscles are always present in some number, and are usually abundant. The largest forms (megaloblasts) as a rule predominate, but in some cases the smaller forms are more abundant. Karyokinetic figures may be found in the nuclei. Polychromatophilia is generally present. The leucocytes may be decreased or normal in number; in the late stages leucocytosis is not uncommon, and it may become extreme. The larger mononuclear leucocytes are usually more abundant than in health, and myelocytes often occur in considerable numbers. In the terminal leucocytosis of pernicious anemia the lymphocytes often predominate.

6. In *chronic parenchymatous nephritis* both degenerative and proliferative changes are seen. The tubular epithelium is always more or less affected, showing signs of cloudy swelling, fatty degeneration, desquamation, and disintegration, most marked in the convoluted tubules, but also present in the loops and collecting tubules. The distribution of these changes is usually patchy, giving rise to mottling of the cortex. The lumina of the tubes may be dilated, and contain granular and fatty matters, and hyaline casts, the latter formed by coagulation of exudation in the tubules. The glomeruli may occasionally appear normal, but there is almost always some swelling and hyaline degeneration, together with some proliferation and desquamation, of the epithelium, so that they become highly cellular. Occasionally the glomerular changes may be more marked than the tubular; fatty degeneration of the glomerular and capsular epithelium may be prominent, or there may be swelling, proliferation, and desquamation of the epithelium, or both these changes may be combined. The glomerular vessels may be compressed, their endothelium degenerate, and they may be obstructed by leucocytes or by hyaline thrombi, and finally obliterated. Interstitial changes, though present, are not conspicuous, and consist of edema, and scattered foci of round-celled infiltration about the glomeruli and veins. Sometimes hemorrhages are evident in some of the glomeruli and the corresponding tubules. Lardaceous infiltration frequently accompanies parenchymatous nephritis.

7. A *malignant growth* is a tumor with the following characteristics: There is no capsule to the tumor, and so it invades the surrounding tissues, it spreads to distant organs, it produces a cachexia, it tends to recur after removal, and leads to inevitable death. *Examples:* Carcinoma and sarcoma.

8. *Acute interstitial myocarditis:* "The affected heart muscle is soft and often distinctly friable. In the earlier stages there may be spots of hemorrhagic infiltration, but as a rule the color is rather lighter than that of the normal organ. It may be noticeable that the bundles of fibers easily separate from one another. The cavities of the heart are frequently dilated, particularly the left ventricle. Microscopically the important changes are diffuse infiltration of round cells in the connective tissue between the muscle fibers and proliferation of the connective tissue itself, with formation of rounded or spindle-shaped fibroblastic cells. There is no tendency to suppuration. The blood-vessels are usually somewhat distended with blood, and there may be distinct proliferative thickening of their walls. Degenerative changes of the muscle fibers themselves are rarely, if ever, absent, and it is most probable that the first stage in the process is a toxic degeneration of the muscle fibers, and that the intermuscular infiltration and proliferation are consequent upon the primary degeneration. The fibers become granular and opaque, the striations are indistinct; occasionally there may be vacuolization, and sometimes segmentation. Proliferation or swelling of the nuclei of the muscle fibers is frequent, and the hyaline transformation of Zenker is sometimes observed."—(Stengel's *Pathology.*)

9. *Amyotrophic lateral sclerosis* shows degeneration of the crossed pyramidal tracts extending upward (to pons, medulla or even to the cortex), atrophy of the ganglion cells of the anterior cornua, degeneration of the nerve fibers in the anterior roots and atrophy of the muscles.

10. Tubercle is subject to changes, of which the most frequent and characteristic is *caseation.* It is a regressive change, whereby the primarily transparent tubercular tissue is converted into an opaque yellowish substance of various degrees of consistency, resembling certain varieties of cheese, whence the name. The process is a form of coagulation necrosis, beginning in the center of the tubercle. The cells lose their outline, their nuclei are no longer demonstrable by ordinary staining methods, and a confused granular mass results. Bacilli are, however, present.

Most frequently caseation is followed by *softening.* The precise conditions necessary for this are not known, though commonly, as soon as a caseated mass reaches a certain size, it breaks down into a pyoid product which is not histologically pus, but consists of a number of fat drops, granular débris and shriveled, formless cells. In the broken-down material the tubercle bacilli are exceedingly numerous, much more so than in the dry caseated tubercle. (From Tyson's *Practice of Medicine.*)

PRACTICE OF MEDICINE.

1. *Dysentery* is a disease, sometimes infectious, and blood is often passed by the rectum; tenesmus is a prominent symptom. *Diarrhea* is a symptom (and not a disease), is not infectious, and as a rule the stools are not bloody, there is no tenesmus.

2. In *empyema*, besides most of the signs of the pleurisy, there may be: Chill, fever, leucocytosis, pus found on aspiration and auscultation over the pus will not detect the whispered voice (Baccelli's sign).

3. The apex beat is displaced downward and to the left; the area of cardiac dulness is increased; a diastolic murmur may be heard at the base on a level with the second or third intercostal space, transmitted down the sternum and to the apex; and the Corrigan pulse is present.

5. *Endocarditis may be caused by:* Bacteria, rheumatism, chorea; it may follow septicemia, gonorrhea, tuberculosis, scarlet fever and nephritis.

4. *Area of Liver Dulness.*—This extends in mammary line from the upper border of the sixth rib to the costal margin; in the axillary line, from the eighth rib to the eleventh rib; in the median line, the upper border is lost in the cardiac dulness, while the lower border lies midway between the ensiform cartilage and the umbilicus

6. Human beings acquire tapeworms through eating meat (generally raw or only partially cooked) containing the cysticercus.

7. GASTRALAGIA. *Causes:* Dietetic errors, overwork, anemia, nervousness, hyperacidity, gastric ulcer or cancer, locomotor ataxia, nervous dyspepsia.

Symptoms: Severe pain in the epigastrium when the stomach is empty, and relieved by food or pressure. The pain often radiates to the back, sides, or shoulders; eructations and restlessness are noticed

8. *A cavity in the lung* in tuberculosis will show the

respiratory murmur amphoric or cavernous; vocal resonance increased and high-pitched; whispering pectoriloquy; râles gurgling or bubbling; percussion gives a dull, tympanitic or cracked-pot sound.

9. *Bronchorrhea* is a condition characterized by excessive bronchial secretion.

10. The overgrowth of connective tissue causes atrophy of the hepatic cells; this causes obstruction of the circulation through the portal capillaries; the blood pressure in the portal vein rises, and ascites follows (due to the permeability of the capillary walls).

OBSTETRICS.

1. *Pathology of vesicular mole.* "The idea has long prevailed that the disease was a myxomatous degeneration of the mesoblastic core in the *interior* of the villi, but more recently it has been demonstrated that the epithelial *coverings* of the villi—the layer of Langhans and the syncytium—are chiefly concerned. While the inner substance of the villi does undergo a myxomatous degeneration with obliteration of the fetal capillary loops, it is really the rapid proliferation and increased activity of the cells of Langhans and of the syncytium upon which the development of a vesicular mole chiefly depends." (King's *Obstetrics.)*

2. *Rachitic pelvis* is due to the presence of rickets in youth. During the process of growth the lack of lime salts causes a softening of the bones; these latter yield easily to the weight and pressure of the superimposed body. It is recognized by pelvic obliquity and the characteristic epiphyseal changes. The pelvis is asymmetrical; the cavity is shallow, the brim is distorted, the pubic arch is widened, the sacral promontory is prominent.

3. *Placental syphilis* may cause the death of the fetus; or abortion; or the fetus may be undersized, or poorly nourished.

4. *Cause of intrauterine amputations:* The presence of amniotic bands or adhesions.

5. The placenta dates from about the third month.

6. The principal cause of eclampsia is autointoxication.

7. The uterus is anteflexed and also descends a little into the pelvis; this descent is followed by a progressive ascent.

8. Sepsis leading to endometritis, salpingitis, ovaritis, peritonitis; also displacement of the uterus; cystocele and rectocele resulting from lacerated perineum.

9. *Operation for tubal pregnancy (before rupture).* "After thorough cleansing and sterilization of the abdomen and pubes, as well as of the instruments and hands of the operator and assistants, the bladder is emptied and the patient anesthetized. An incision three inches long is then made in the median line above the pubes down to the peritoneum, any bleeding vessels being twisted before opening the peritoneal cavity. The peritoneum is then incised; the intestine kept back by pads of cotton or gauze wrung out of the sterilized water; the operator's fingers bring out the distended tube and ovary at the incision after having freed them from any existing adhesions; the pedicle is then transfixed by a double ligature of sterilized silk, and each half of it tied securely according to surgical rule. The pedicle is cut, and the entire mass—tube, fetal cyst, and ovary—removed. The pads are then withdrawn and the abdominal incision closed and dressed in the usual manner. In case of threatened collapse from hemorrhage during the operation, the peritoneal cavity may be flooded with a 1 per cent. sterilized solution of common salt at a temperature of 100° F., a quart of this solution having been previously prepared. It is rapidly absorbed by the peritoneum, and acts as a restorative—like transfusion." —(King's *Obstetrics.*)

10. *Ruptured uterus* is announced by a sudden, acute, and persistent pain. Sometimes the sound of the rupture is heard by the patient; the symptoms of internal hemorrhage and shock are present—collapse, air-hunger, cyanosis, rapid, feeble pulse; the uterine contractions cease. The abdominal cavity must be opened, the uterine rent closed by sutures, all blood and fluid removed from the abdominal cavity, and the very strictest antiseptic precautions observed. If the tear is severe, hysterectomy is indicated.

SURGERY.

1. *Air embolism* is characterized by a sudden, hissing noise as the air enters a vein; there are dyspnea, syncope, and collapse. *Treatment* consists of immediate pressure on the part; the head should be lowered, the vein must be picked up and ligated; afterwards artificial respiration and stimulation may be necessary. It most frequently occurs in surgical operations in the neck or axilla.

2. In treating infected wounds, the first principle is to disinfect.

"Infected wounds should be opened freely to secure drainage, and hopelessly damaged tissue should be curetted or cut away. The wound should be washed with peroxide of hydrogen and then with corrosive sublimate, dusted with iodoform or orthoform, either drained with a tube or packed with iodoform gauze, and dressed with hot antiseptic fomentations. The part must be kept at rest and internal treatment should be stimulating and supporting. If lymphangitis arises, the skin over the inflamed vessels and glands is to be painted with iodin and smeared with ichthyol, and quinin, iron, and whiskey are given internally. The temperature is watched for evidence of general infection or intoxication. The patient must be stimulated freely, nourishing food is given at frequent intervals, pain is allayed by anodynes if necessary, and sleep is secured."—(Da Costa.)

3. For *rattle-snake bite:* Tie a ligature above the part immediately, then excise the wound, cauterize, and give stimulants. Antivenine is said to be useful.

4. The forearm is first supinated, then overextended to release the coronoid process; traction is made on the forearm, while the lower end of the humerus is fixed; and on flexing the joint, the bones slip into place with a snap. Or, the surgeon may use his knee or other part as a fulcrum, and by traction round it may disengage the coronoid process, and allow the bones to jump into place.

Aftertreatment consists in putting up the joint in an inside, angular splint, and the arm in a sling, and evaporating lotions applied to prevent inflammation. Passive movements should be cautiously begun on the fingers, at the third day, then of wrist and elbow (with massage) as soon as it can be effected without pain.

5. *Operation for Removal of the Appendix.*—"An incision is made at right angles to a line (at the junction of the outer and middle thirds) joining the umbilicus and anterior superior iliac spine, one-third being above and two-thirds below it. The cecum is found, and the anterior longitudinal band is traced down to the appendix, which usually comes off from the inner side and runs inwards and downwards. If not found there, it should be looked for in the retrocecal pouch or on the outer side of the cecum. The meso-appendix should be ligatured and cut through, a collar of peritoneum turned back, and the mucus and muscular coat ligatured near the base and cut off. The peritoneum should be stitched over the stump, and then the stump should be invaginated into the wall of the cecum by running a purse-string stitch around it."—(*Aids to Surgery.*)

6. *Pott's disease* is tuberculosis of the spine. *Treatment:* "Rest in bed, using sand bags as splints, is the first consideration. After the acute symptoms have subsided a Thomas splint, Sayre's plaster cast, or Cocking's felt jacket may be applied to the back and the patient gradually allowed to move about. *To apply the plaster-of-Poris case,* the patient should be suspended so that the heels are just off the ground. A skin-fitting vest is then applied to the trunk, under which a stomach-pad is inserted, which should be removed after the plaster has become dry. Plaster bandages should now be applied in the usual manner, extending from the level of the axilla to just below the crest of the ilium. When the case is dry, it may be divided down the front and perforated, so that it can be laced up or removed at any time. Abscesses should be opened early and freely, and injections of iodoform emulsion will be found very beneficial. Laminectomy is sometimes advisable."—(*Pocket Cyclopedia.*)

7. Burns of the first degree are characterized by hyperemia; of the second degree by dermatitis and the formation of vesicles; of the third degree by partial destruction of the skin (Dupuytren).

"The constitutional effects must be treated first. Put the patient in bed with warm blankets, without disturbing the clothing over the burnt parts. Administer brandy by the mouth or rectum, and morphine to deaden pain, and prevent further shock. Saline infusion into the loose subcutaneous tissues or into a vein may be tried if the pulse is very small. Ether and strychnine may also be used.

When the patient reacts to these, the local injuries may be treated. For burns and scalds of the first and second degree, ointments are the most soothing. Powders such as zinc oxide and bismuth are also cooling and keep the part in good condition. For burns which destroy any part of the true skin, ointments and antiseptics are dangerous, the one on account of sepsis which occurs beneath it, and the other from the danger of absorption of the poisonous drug. Picric acid in 5 per cent. solution may be painted over shallow burns, as it forms a skin, and is to some extent antiseptic. Boric acid, as powder or in moist lint, is one of the best dressings, provided it is changed very

frequently. The part may be treated with peroxide of hydrogen daily in addition. When granulations have formed, the part is treated as an open wound with aseptic dressing. All dead pieces of skin should be snipped off at each dressing as they die; and as soon as possible skin grafts are applied. Subsequent contraction of scars is treated by plastic operation."—(Buchanan.)

8. *Neurectomy* is sometimes employed for the cure of neuralgia (trifacial). Success may be expected when only a limited part of the nerve is affected—particularly the distal part.

"*Extracranial section of the third division at the foramen ovale* is best accomplished in the following manner: A flap of skin and subcutaneous tissue is reflected forwards from the parotid region, extending from the zygoma above to the angle of the jaw below, exposing thus the parotid gland with the socia parotidis and the masseter muscle, covered by fascia. If the incision is kept strictly to the subcutaneous tissues, the facial nerve is in no way endangered. The masseter is then divided transversely immediately below the socia parotidis, and the vertical ramus of the inferior maxilla cleared of muscle and periosteum to a sufficient extent to allow the application of a ¾-inch trephine just below the sigmoid notch, the remaining bridge of bone being subsequently removed by cutting pliers; enough bone is left in front and behind to preserve the continuity of the jaw. The fibres of the external pterygoid muscle can now be seen crossing the upper part of the wound horizontally, and over it the internal maxillary artery sometimes courses. The lingual and dental nerves are usually found close together, emerging from under the outer pterygoid muscle, and lying between the internal pterygoid and the bone. The peripheral portions should be twisted or pulled up and divided below as far down as possible, whilst by retracting the external pterygoid outwards, the foramen ovale can be seen, if electric illumination is employed, and the nerve-trunks divided at the point of exit. The wound usually heals well, and leaves but little scar, although some impairment in the mobility of the jaw may result from the cicatrization following disturbance of the muscles and tissues."—(Rose and Carless' *Surgery.*)

9. *Signs of a total transverse spinal lesion.* 1. In the area supplied by the nerves below the lesion.—Complete motor paralysis, followed by late rigidity and contraction of the muscles. Complete anesthesia, with loss of senses of pain or temperature. Complete and permanent loss of the deep reflexes. Temporary loss of the superficial reflexes. Vasomotor paralysis, with trophic lesions. Visceral paralysis (bladder, rectum, intestines), according to site. 2. In the area supplied by the nerves at the site on the lesion.—Paralysis, with rapid and flaccid atrophy of the muscles. Zone of hyperesthesia from nerve-root irritation.

Signs of a partial lesion.—The central parts of the cord may escape injury. In this case the deep reflexes are retained or soon regained; the senses of pain and of temperature are retained; the anesthesia may only be partial.

In cases of recovery from concussion or contusion the functions of the cord are regained in the following order: Deep reflexes—sense of pain and temperature—tactile sensation—motor power.—(Grove's *Synopsis.*)

10. *Treatment of lymphangitis:* The primary focus may be cleaned and asepticized. Hot fomentations may be applied; abscesses must be opened. Rest, tonics, good feeding are necessary.

GENITOURINARY AND DERMATOLOGY.

1. The patient should be kept warm in bed, the bowels should be opened, quinine is indicated; if suppression of urine occurs, sweating, hot baths or leeches over the loins may be tried; saline solution intravenously or by hypodermoclesis may be useful.

2. Gonorrheal rheumatism. *Symptoms:* "The acute form attacks, as a rule, but a single joint, but many attack several joints. The joint trouble begins with great suddenness, and is often ushered in by chilly sensations or by a distinct chill. Moderate fever arises. The pain in the joint, severe from the first, becomes excruciating. If superficial joints suffer, the skin over them becomes red and hot, and periarticular edema soon presents itself. The fluid in the joint is in most cases serous, but may become purulent. If pus forms, the fever becomes very high and chills may occur."

Treatment: "The salicylates, the alkalies, and salol are useless; iron, arsenic, and strychnine are possibly of some benefit. Quinine is helpful in some cases. Iodide of potassium seems to be of a certain amount of value. The inflamed joints should be wrapped in cotton and bandages, and every day a little blue ointment should be rubbed into the skin about them. If the inflammation lingers, use the hot-air oven, massage, and gentle passive motion, apply blisters, or counter-irritate with the hot iron. If the inflammation still lingers, or if it becomes worse, aspirate, wash out the joint with hot normal salt solution, and inject iodoform emulsion. If pus forms, incise, irrigate, drain, and immobilize."—(Da Costa.)

3. *Symptoms of stone in the bladder:* Pain in bladder and perineum, referred to the end of the penis, and made worse by micturition. Constant urination, followed by pain and spasm, straining, cessation of urination or retention of urine. A click may be elicited by a sound or searcher.

4. Acute Prostatitis. *Symptoms:* "Micturition is very frequent, with pain at the end of the act; there is a feeling of weight about the rectum, and pain on defecation. There is marked pyrexia, and even rigors. The prostate is felt to be enlarged and tender, with soft spots when suppuration is established. Retention of urine accompanies suppuration. *Treatment:* Absolute rest is necessary. The bowels must be kept well open. The pain is relieved by hot baths or hot fomentations and morphine suppositories; failing this, half a dozen leeches are applied to the perineum. If a catheter is needed, a soft rubber one should be used. If this treatment fails, it is because an abscess is forming, and should be treated by a median perineal incision."—(*Aids to Surgery.*)

5. *Treatment of chronic posterior urethritis:* "When the desire for frequent urination begins to disappear, and the urine becomes less cloudy, a Jacques catheter (No. 18 F.) should be passed as far as the membranous urethra, and the bladder injected with a hot solution of potassium permanganate 1:2000, or of silver nitrate 1:10,000; the instrument should then be removed and the patient instructed to empty his bladder in the usual manner, thus flushing the entire canal with the medicament. In congested and irritable conditions of the prostatic urethra, associated with pain and discomfort, with little or no frequency in passing urine, the urine being clear except for a few threads, benefit will be derived from the employment either of a bougie or the cooling sound. Should the urine contain much pus, the desire to urinate being frequent, any of the antiblennorrhagic remedies may be employed. Often relief will be experienced from the administration of a capsule containing ¼ of a grain of codeine sulphate combined with 5 grains of salol."

6. *Verruca* is a papillomatous overgrowth of the skin; often multiple; may appear in crops; it may be due to irritation. Sometimes it may be infective. It should be painted with glacial acetic acid or some other caustic every two or three days after the horny crust has been softened with salicylic acid and removed.

7. *Seborrhea* is a disorder of the fat-producing glands characterized by an increased and altered secretion of sebum, producing an oily or scaly condition upon the skin. *The treatment* should first be directed to the general health of the patient. Gastrointestinal disorders should receive attention, and arsenic, iron, quinine, strychnine, and calcium chloride are often indicated. The crusts and scales should be removed from the affected parts by the use of tincture of green soap or oil, after which applications containing resorcin, sulphur, or salicylic acid should be made.

8. *Hypertrichosis* is a condition characterized by excessive growth of hair.

9. *Vitiligo* is an acquired condition characterized by areas devoid of pigment surrounded by hyperpigmented borders. It occurs usually in adult life and seems to be dependent upon some disturbance of innervation. Apart from this, the cause is obscure. The affected areas are attended by no changes other than loss of pigment which may also be absent from the hair in those regions. Its onset is slow and its course indefinite. It usually persists during the lifetime of the individual. The treatment is unsatisfactory. Arsenic internally, and counter-irritation to the patches may be tried.—(Hughes' *Practice of Medicine.*)

10. *Epithelioma*, or squamous-celled carcinoma, may arise on any surface covered with stratified epithelium. It usually arises in the middle-aged or elderly, but may also occur in the young. It often results from long-continued irritation, and may arise in old scars or ulcers. It may appear in one of three forms: (1) A wart-like growth with an indurated base; (2) a small circular ulcer with raised, rampart-like edges; (3) an indurated fissure. The growth extends to the deeper structures; the surface ulcerates and becomes foul from contamination with putrefactive organisms. The nearest lymphatic glands always become infected sooner or later, and a fatal termination occurs rapidly unless treatment is early and thorough. *Treatment:* Early and free removal of the growth and the adjacent lymphatic glands, if affected.—(*Aids to Surgery.*)

THE ETIOLOGY AND PATHOGENESIS OF BRONCHIAL ASTHMA.

BY APOSTOLOS G. APOSTOLIDES, M.D.,

SMYRNA, ASIA MINOR.

PHYSICIAN TO THE CIVIL OTTOMAN HOSPITAL.

UNDER the heading of asthma there are many varieties of dyspnea corresponding to different causes or different pathological features. As a symptom it has been discussed in connection with the various morbid conditions and the little that is known about its treatment I discussed in an article published last year in the *Folia Therapeutica* of London.[1] In this paper I shall deal with the marked increase of respiration occurring in paroxysms—the so-called idiopathic, bronchial asthma.

Definition: "Essential" bronchial asthma is a functional neurosis, that is, a condition of which as yet no organic basis has been discovered, characterized by sudden paroxysmal attacks of great dyspnea, with a peculiar exudation of mucin and with distention of the lungs. The attacks may last a few hours or days, or may be protracted for a week. In this form also the phenomenon occurs after a variety of causes; in other words, bronchial asthma is often a mere symptom. But we must inquire whether the phenomenon always represents merely a symptom or whether it may perhaps, in some cases, be the cardinal symptoms of an otherwise obscure disease. Until the properties that characterize the condition are known, it will, therefore, be necessary to continue to speak of "essential asthma" as a clinical entity and for this purpose the relations or differences existing between the conditions of individual patients suffering from paroxysmal dyspnea must be investigated. Under the heading of essential asthma we must therefore include those clinical conditions in which the respiratory organs are normal and the attacks are produced *exclusively by some perversion of the nervous system*, in which finally no objection can be formulated from an anatomical point of view. This definition sharply isolates this disease and more especially differentiates it from all those symptom-complexes which, though also due to abnormal innervation of the respiratory nervous system, are really nothing more than symptoms of definite anatomical lesions of the lungs or of more distant organs. The pathology of bronchial asthma has been the subject of incessant debate; unfortunately the advancement of our knowledge was long delayed because every investigator was bent on solving the question whether paralysis of the bronchial muscles or contraction of the inspiratory muscles was the cause of the asthmatic dyspnea, and in doing so neglected every other point of view; in other words, the disputants have concerned themselves not so much with the cause of asthma as with the anatomical conditions in the bronchi which occasioned it, and these conditions have been narrowed down to spasm on the one hand and hyperemia on the other.

The mechanism of the intense dyspnea which characterizes the asthmatic paroxysms may be considered as definitely settled. *It is the consequence of a sudden narrowing of the smallest bronchial lumen.* So sudden is its onset and so intense may the dyspnea shortly become that even *prima facie* the idea of a spasm seems alone adequate to account for it. This theory, which has perhaps the largest number of adherents and according to which the

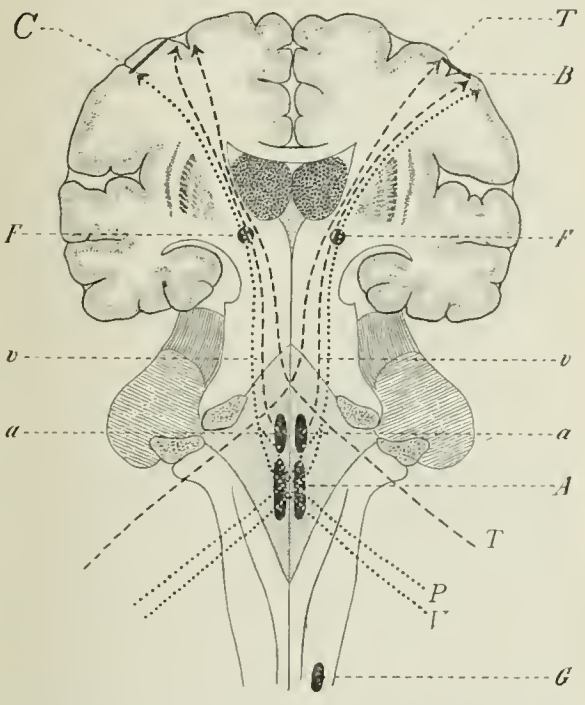

Fig. 1.—Diagram of the respiratory centers and their paths from the brain and medulla. *A*, Principal bulbar respiratory centers; *B*, cortical higher respiratory centers; *C*, higher vasomotor centers; *F*, respiratory center in corpora quadrigemina; *G*, spinal respiratory center (?); *P*, pneumogastric nerve; *T*, trigeminus nerve; *V*, vasomotor fibers in vagus nerve; *a*, bulbar vasomotor centers; *v*, path of vasomotor fibers.

dyspnea is due to spasm of the respiratory and bronchial muscles, was pronounced in the seventeenth century by Willis and supported by the great authority of Cullen, Biermer, Salter and others and confirmed by the original experiments of C. J. B. Williams and Brodie. But if all these authors agree on this point, namely, that the muscle spasm is the starting point of the asthmatic dyspnea, they still disagree as to which muscles the attack is to be ascribed to. Some writers, notably Bargson. Salter, Knopf, Feer, Weber, and others, are of the opinion that the spasmodic contraction of the bronchial muscles (bronchospasm) and the vesicles

of the lungs is sufficient in itself to account for asthmatic dyspnea, while others, Wintrich, Bamberger, G. See, and Apostolides senior, attach greater importance to the inspiratory muscles and especially to the diaphragm. But the view held almost universally is the one which maintains that the asthmatic dyspnea is due to a tetanic *contraction of the inspiratory muscles and diaphragm as well as to a spasmodic contraction of the bronchial muscles and vesicles of the lungs.* This theory has in a short time replaced the older view of Traube and Clark and others, that the attack is due exclusively to swelling of the bronchial mucous membrane—fluctionary hyperemia (Traube), diffuse hyperemic swelling (Clark), vasomotor turgescence (Weber). Personally I am inclined to believe that criticism went too far in theory and that both the contraction of all the inspiratory muscles (extrinsic and intrinsic muscles and the diaphragm) as well as the swelling of the bronchial mucosa work hand in hand in this matter. But I do not think it is correct to regard contraction of the muscle and swelling of the mucous membrane as the most prominent factor of the dyspnea. It is quite possible that these factors form only a part and probably a minor part of the pathological processes which occur in the bronchial tubes. I am therefore inclined to assume that an abnormal nervous condition is present. This, it seems to me, is supported by the close and striking similarity between these attacks and those of so-called mucous colitis and urticaria. With regard only to the asthmatic dyspnea, Curschmann is quite right in defining asthma as a special form of inflammation of the smallest bronchioles, as so-called "bronchiolitis exudativa," but on the contrary he is quite wrong when he tries to deduce the whole symptom complex of asthma from this factor; the hyperemia and swelling of the mucosa and the extremely viscid, tenacious mucus explain well the hindrance to inspiration and expiration and also the quality of the râles, but they do not explain the suddenness of the attack and the prolonged expiration. I share, therefore, the view of some modern writers, Strümpell,[2] Schmidt,[3] Fr. Hoffmann,[4] and others, who state that bronchospasm, contraction of the inspiratory muscles, turgescence of the bronchial mucosa, and the influence of the nervous system all simultaneously contribute to the asthmatic dyspnea.

A very strong support to this view is afforded by the anatomy of the lungs. With regard to the bronchial muscles, Aufrecht[5] has discovered the existence of a fine longitudinal layer closely interwoven with the circular fibers. Then with respect to their innervation, careful experiments by Dixon and Brodie and Einthoven have demonstrated that the sole supply is from the vagus, which contains both *bronchoconstrictor* and *bronchodilator* fibers (anterior and posterior pulmonary plexuses), and that the pulmonary vessels are devoid of vasomotor nerves; other writers, however, state that the vagus fibers belong to the musculature and the sympathetic to the blood-vessels, and even that these latter come from the first thoracic ganglion (Hoffmann).[6] With regard to bronchial vessels anatomists[7] state that in the bronchioles the principal supply is not from the bronchial but from the pulmonary artery. All these become of importance in connection with the pathological anatomy of asthma. In asthmatic attacks the contraction of the strong circular layer overcomes that of the interwoven weaker longitudinal layer and the narrowing of the lumen of the bronchi is brought about. The turgescence of the mucosa and the catarrhal condition on the other hand complete the narrowing. The relation of the contraction of the bronchioles and the turgescence of the mucosa will be discussed further on. It is sufficient here to say that if on various occasions of provocation the bronchial tubes are so liable to contractions more or less excessive, is there likely to be any reason for denying a similar possibility or necessity ever to occur in the case of the vascular tubes? After this summary review of what is known about the mechanism of the asthmatic dyspnea, let us pass on to inquire as to the nature of the disease. It is very difficult as yet to give anything like a final opinion on this point, because, although it seems incredible, our knowledge of the mechanism by which the air is carried to the alveoli is unquestionably quite inadequate. By what mechanism does the air gain access to the alveoli? What part do the bronchial muscles take in respiration? Difficult as well as important experimental investigations by prominent physiologists have taught that the action of the respiration is influenced in a variety of ways—by the irritation of various centers and nerves, and that its rhythm particularly can be altered in many different ways. Before we can hope to gain a true understanding of the pathogenesis of asthma bronchialis we ought to be properly informed with regard to the many nervous influences that regulate the action of respiration and blood-vessels in the normal individual. But at once we are met by the lack of a firm physiological basis and therefore we must be satisfied with general remarks gained by experiments on animals. Thus, the experiments of Martin, Brooker, and Christiani and the anatomical studies of Gad and Marinescu, and more recently the experimental work of Sherrington and Grünbaum have shown that the true principal respiratory centers are found in the medulla oblongata, and occupy not only the top of the calamus scriptorius, as Flourens believed, but are situated in the floor of the fourth ventricle, occupying an area on both sides of its middle line. These principal respiratory centers are in close connection with the rest of the brain in which are located the so-called *cortical higher respiratory centers.* The localization of these *higher respiratory centers* is not definitely determined in the cortex of the brain, but it is believed to be for the most part in a strip near to the fissure of Rolando, where are also located the motor areas of the cortex and the higher centers of the vasomotor nerves. (Frank). Some authors[8] believe that there are other respiratory centers, namely, one higher in the corpora quadrigemina and one lower in the spinal cord. The paths for the conduction of the stimuli which underlie the special respiratory centers are found in the different fibers of trigeminus, which convey cerebral impulses to the bulbar respiratory centers. The cortical centers are bilaterally acting and a lesion limited to either one should not produce marked defects in respiration. The lower segment of the primary respiration's mechanism is made up of the motor nuclei in the medulla, and in the peripheral nerves arising from them, especially pneumogastric and sympathetic. We know very little of the pulmonary branches of the vagi.[9] The motor fibers are stated to control the action of the bronchial muscles, and the various alterations in the respiratory rhythm are due more to changes in the center than in the nerves themselves. The vasomotor

fibers of the lungs, parting from their centers, situated according to R. Nicolaides and Kronecker[10] in the floor of the fourth ventricle, pass for the most part in the vagi and, giving off at different levels fine medullated fibers, end in arborization about the ganglion cells of the thoracic sympathetic.[11] It has been shown with absolute certainty that the bulbar respiratory centers work automatically. Respiratory sensations and respiratory movements *depend upon the interchange of gas between certain cells in the central nervous system*, and on their ability to take up oxygen and give off carbon dioxide. *Respiration thus depends, in the great part, on the condition of the blood.* This does not exhaust the question, however, for we still have to reckon with the effect of the higher centers on the respiration. Everybody knows that the condition of the brain exerts a profound influence on the respiration; it has long been a matter of popular belief that psychic excitement may directly arrest the respiration. Besides these centers, the pneumogastric nerves have an important effect on the respiration. Unfortunately, our knowledge of the extent to which respiratory sensations or modifications of the respiratory movements can be initiated through the agency of the nerve-endings in the lungs is very limited (Nicolaides).[12]

Summing up what is said above, it will be seen that the respiration-rhythm is governed by some centers, the most important of which are the bulbar centers, the cerebral centers, and the spinal respiratory centers. The higher centers and the spinal centers are connected directly by special motor fibers with the bulbar nuclei which are the true respiratory centers. The cortical respiratory centers are in close connection with the rest of the brain. Such is the state of our knowledge regarding the mechanism; let us pass on now to inquire as to the seat of the starting point of the attack. Of the numerous theories advanced to explain this matter the following are the most important: (1) Asthma is a neurosis, the seat of which is the pulmonary apparatus and especially the bronchial membrane. (Curschmann,[13] Ungar,[14] Bretonneau, Rostan, Louis, Fürbringer,[15] and Strümpell.) All of these authors are of the opinion that the so-called asthmatic diathesis is due to a special form of inflammation of the bronchial mucosa and therefore they have given it different names as "bronchiolitis exudativa" (Curschmann), "asthma-catarrh" (Hoffmann), "asthmatic bronchiolitis" (Strümpell). Some even went so far as to consider the asthmatic exudation to be of a very characteristic and peculiar character. But the characteristic asthmatic secretion has just been discussed by many authors. Vierordt, von Jacksch, Vincenzo, Matessori,[16] von Noorden,[17] and others[18] have found Leyden's crystals, Curschmann's spirals, and eosinophile leucocytes in many diseases of the lungs, as pneumonia, phthisic bronchitis, bronchorrhea, etc., so that no one believes any more in their specificity; they are regarded rather as indicating a revolving force acting upon the mucous membrane of the finest bronchi. I believe that there are numerous signs pointing directly to an inflammatory process in the bronchioles and at all events that this inflammation is peculiar both anatomically and etiologically. But to this important point I shall soon return. It will suffice in this place to state that sometimes the asthmatic attack comes like a bolt from the blue; that is, it is the first sign of the disease and passes without any expectoration. But even if the latter view, that of the inflammation of the mucosa, were adopted, this point unquestionably requires still further investigation, and, above all, it ought to be determined in what class of cases this inflammation occurs. What is the nature of the anatomical process that lies at the bottom of it? Certainly not a banal inflammation of the bronchioles. For such an alleged inflammation could not suddenly cause as much greater obstruction of the air tubes than is produced by acute inflammation of the bronchioles, which even generalized (capillary bronchitis) is not attended with a dyspnea anything as severe as we find in asthmatic attacks. The theory, according to which the asthmatic attacks are due to changes of the cells of the alveoli which, under certain circumstances, as for example under the influence of *x*-rays, secrete more mucus than normal (Immelmann, Eckstein) is mentioned only to be dismissed; for it seems to me a hazardous undertaking to draw conclusions from the results of the influence of *x*-rays upon the cells of the bronchioles. There is too much danger of fallacy from suggestion. Moveover, even the most

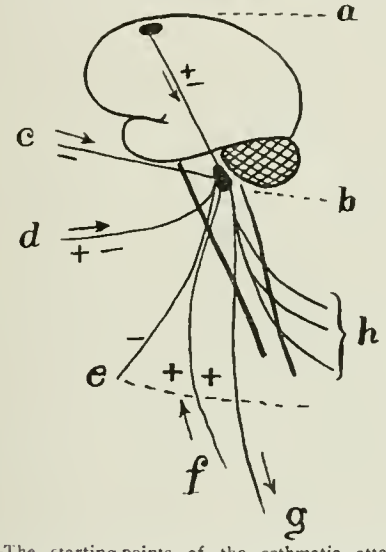

Fig. 2.—The starting-points of the asthmatic attacks; + indicates augmentation; —, inhibition of the respiratory power. *a*, Cortical psychic centers; *b*, bulbar respiratory centers; *c*, nasal stimuli; *d*, cutaneous stimuli; *e*, laryngeal stimuli; *f*, pulmonary stimuli (pneumogastric nerve); *g*, phrenic nerve; *h*, intercostal nerves.

fanatic upholders of the inflammation theory (Schmidt, Fürbringer, Strümpell, Hoffmann) acknowledge that *in the asthmatic attacks certain nerve tracts must be over-irritable.* We are thus led to the second theory, according to which the asthmatic diathesis *results from disturbed innervation.* But here, too, opinions differ a good deal on this question as to the seat of the starting point of the disturbed innervation, namely, as to what parts of the nervous system are responsible for this anomaly. Many are of the opinion that disturbances of the vasomotor centers, which govern the reflexes of the circulatory and respiratory apparatus, are responsible for the asthmatic attack (Ad. Strümpell, Brügelmann,[19] Schmidt, and others).

Physiologically considered these arguments are strong because we know that the bulbar vasomotor centers, which, as mentioned above, are situated close by the respiratory ones, are sensible to the chemical condition of the blood and may react manifestly to injuries (Achard-Levi).[20] A very strong support to this view is afforded by the striking similarity between these attacks and those of the mucous colic and urticaria, which both rest on specific disturbances of the vasomotor nerves. If

this theory is accepted the analogy to similar processes in the bronchial tubes appears quite accurate.[21] In the case of mucous colic, spasm may also have been present. I am willing to adhere to this theory, but I cannot regard the vasomotor centers as responsible for the contraction of the inspiratory muscles (musculi levatores costorum, musculi intercostales) and the diaphragm, which nowadays are regarded as important factors in the asthmatic attacks. Nevertheless this view seems to me to be of some value, because in both diseases the clinical material is uniform (neurasthenia, neurosis) and because some patients may have both diseases. If the vasomotor theory cannot be accepted in its entirety, there can be no doubt that what it holds is true, namely, that without these disturbances of the vasomotor nerves there would not be swelling of the mucosa and hyperemia. But as far as I can see there is no reason to believe it possible that bronchial asthma is due to disturbances of the secretory fibers of the vagus or of its sensory fibers, as has been advanced by French authors and especially by Parrot and Todd. The same applies to the view of some modern writers who consider asthma as a vagus neurosis. Remarkable cases have been reported which, in addition to asthma-like attacks, presented a strikingly different phenomena; for example, acceleration of the heart's action, which we are forced to regard as neurotic. The term vagus-neurosis should include those symptom complexes which are produced by anything that acts on the endings or trunk of the pneumogastric nerve and disturbs its function. In such a condition one would expect symptoms in various organs supplied by the nerve, especially the larynx, the heart, and the gastrointestinal canal. These above few words must be devoted to this subject because the respiratory symptoms, which are often so prominent in a clinical picture of vagus disease, bear a certain resemblance to the condition seen in paroxysmal asthma, although really the two conditions have nothing whatever in common. Nevertheless, it is often exceedingly difficult to draw a dividing line between essential bronchial asthma and the effects of vagus disease. This point has already been discussed,[22] but I insist again on it because, especially F. Knopf and Gottschalk,[23] among others, promulgated the theory that bronchial asthma is due to injuries of the peripheral nerve endings of the vagus and that enlargement of the bronchial glands in tuberculosis is "very often" the causative agent of asthma.[24] In support of their theory they point out the fact that compression of the vagal nerve endings by pathological growths may produce asthmatic attacks which in the long run constitute an asthmatic diathesis. Again, have the experiments of Riegel-Edinger,[25] Dixon, Brodie, and Einthoven[26] not shown that stimulation of the peripheral ending of the vagus is always followed by a marked spasmodic dyspnea concomitant with a distention of the lungs? In my opinion this theory is erroneous. In the first place, if it were true essential asthma should occur very often in children in which tuberculous enlargement of the bronchial glands is of such common occurrence (Zuber),[27] while bronchial asthma in children is not very often met with (E. Feer,[28] Comby,[29] Audeoud).[30] Besides, this question could only be answered if there existed a purely spastic form of bronchial asthma; but such a case has never been seen (Fränkel, Schmidt, Weber), and I myself do not remember ever to have seen it, although I have been on the lookout for the phenomenon. I cannot therefore bring myself to share this view in its present form, especially since the same investigators have confessed that the asthmatic-like dyspnea produced by irritation of the vagus was never accompanied by any secretion characteristic of genuine asthma. Besides, no intelligent man would attempt to apply data obtained from healthy animals directly to the conditions existing in human beings in disease. This datum merely enlarges our knowledge of the behavior of the organism in general, and in that way furnishes some assistance in the enormous and difficult interpretation of the phenomena observed at the bedside. So, for example, the effect of electrical irritation of the exposed pneumogastric nerves in a healthy dog has been utilized directly to explain motor disturbances in the lungs which are produced in disease by the most complicated and in part psychic causes! Again, Venot (Paris) and Temple Mursell (London) record cases of patients whose vagus was infiltrated by a malignant growth and *who never had shown asthmatic attacks.*

The most plausible theory and the one that now seems to have the largest number of supporters is the theory first advanced in various forms by Willis and Floyer in 1698 and supported by such authorities as Jaccoud, Trousseau, Brissaud, Dieulafoy, Hoffmann, Brügelmann, etc., according to which asthma is *a neurosis of the bulbar respiratory center* (*bulbar asthma, bulbar neurosis*). The opinion of such distinguished clinicians and able investigators as the above mentioned cannot be disregarded and this view has always appealed to me very strongly, but in the course of years distinct doubts have assailed me, for it must be agreed that a similar bulbar neurosis is unknown. Therefore I am inclined to adhere to the theory I advanced some years ago,[31] namely, that bronchial asthma is a neurosis, like hysteria and epilepsy, of the higher cortical center, which, according to Brooker, Martin, Frank, and others, presides over the lower centers and by means especially of the bulbar centers directs and controls the respiratory movements. This association action of the more complex centers takes place under appropriate stimuli parting from the brain. The vasomotor system is also brought into harmonious cooperation with the central nervous system on account of its dependence upon the latter (R. Nicolaides, loc. cit.). The curious cases of sudden asthmatic attacks *from fright or fear* demonstrate the enormous influence of the cortical centers on the respiration. But what we should like to know in this connection is what the exact nature of the more slowly acting nervous factors must be in order to produce this abnormal irritability. And on this point I am unable to give any opinion. Nor is it likely that we shall be able to furnish such information for the present, because we have as yet no means of estimating the psychic function of the brain. Perhaps, and it is quite probable, abnormal impulses from these cortical centers may inhibit the respiratory bulbar centers and bring about the same effect as is produced by stimulation of these centers themselves. It might also be argued that the increased hyperemia and swelling of the bronchial mucosa which are ascribed to disturbances of the vasomotor centers are due to impulses from these cortical centers, affecting the vasomotor system as well as the centers, which innervate the striped muscles, the two systems being associated by the inhibition of the one and rein-

forcement of the other. I do not believe it is possible at the present time to give an absolutely positive opinion on this point. But it is my personal conviction that there is much to be said in favor of the proposition that purely nervous influences are capable of provoking asthmatic attacks. The experiments of Frank and Brooker among others made on decerebrated animals have shown the great influence of the higher centers upon the bulbar respiratory centers.[32] As a rule the general character of the symptoms in the cases of essential asthma reveals the psychic nature of the complaint. Psychic excitement has a most powerful influence in bringing on the attack, while muscular exertion, on the other hand, has no bad effect in the great majority of cases. In other words, it is exactly the same as with the production of an hysterical attack. As the hysterical suffers (according to Freud) from "reminiscences" relating to the *vita sexuals,* so likewise the asthmatic suffers from *"resurrected moments" of the respiratory organs.* Fr. Hoffmann, Trousseau, and Treupel, among others, state that the *mere reminiscence of a previous attack may bring about a new attack.* One hundred detailed clinical histories written by good observers would be of great value. However, I have no reason in denying the important part which the respiratory mucosa takes in the pathogenesis of this neurosis, for just in this transformation of psychical excitement into persistent bodily symptoms or perhaps in a bodily compliance, I find the essential characteristic of neuroses and psychoneuroses. Nevertheless there must be a native individual predisposition. This hereditary or constitutional factor takes the form in asthma of the "respiratory constitution." As in hysteria, in neurasthenia, and in obscessional and phobic psychoneuroses, the disorder is rooted in disturbances of the sexual organs, so in asthma the bodily disorder is rooted in the respiratory mucous membrane. But the essence of the disease is to be sought in an increased abnormal irritability of the nervous structures, and especially the cortical respiratory centers (asthme cérébral or psychogène, Sihle).[33]

There is a final question to be answered: What is the fundamental cause of this disorder? What is the nature of the anatomical process that lies at the bottom of it? This question has excited a lively interest and has been made the object of much ingenious speculation; it has even rightly become the subject of investigation by bacteriologists and investigations on these lines have not failed to leave their imprint upon the inquiry as to the origin of asthma. The long duration of the affection is not necessarily against its being microbial. It may, however, be a toxin or leucomaine, either of distinctly pathological origin or else a product of normal metabolism, which gradually accumulates in the blood by reason of some defect, congenital or acquired, in the excretory function of the lungs. With regard to this point of view the microscopical examination of the asthmatic's secretion, during the attack, seems to give a strong support to this opinion. Eosinophilia, which is always found during the attack, indicates a local chemotactic afflux to the bronchial tubes (Salecker):[34] some investigators have found reason to believe that the granules of excreted cells are of the nature of alexins and are attracted to substances which are associated with the destruction of epithelium. However, these various bodies, which go to make up the expectoration, can only be regarded, according to Auld, as the outcome of the conflict which has been raging inside, and they may not inaptly be likened to fallen soldiers on the battlefield. Then, as regards the systemic blood-changes, P. Salecker (*loc. cit*), who has devoted considerable attention to this point, affirms that both during and after the attack the fluctuations in the blood-picture, more especially as regards the polynuclear leucocytosis, admit of a degree which is only found as a consequence of conditions of toxemia. Parting from this point of view, Auld goes so far as to recognize that an asthmatic attack is truly and strictly a process of defense. Some physicians during the second half of the nineteenth century, especially Bouchard, Huchard, and Gautier, advanced the view that asthmatic diathesis may be merely the result of a toxin or leucomaine or ptomaine, which is a product of normal metabolism gradually accumulated in the blood by reason of some defect of the excretory function of the kidneys. Huchard has indeed stated that ptomaines stored in the blood in significant quantities, when they are not sufficiently excreted by the kidneys, may produce a toxemia with *a nocturnal attack of shortness of breath* (dyspnée ptomainique nocturne de Huchard). But if these conditions are present the patient, in my opinion, is certainly suffering from a grave disease of the heart muscle or the kidneys, even if no physical signs are present in the organ.

It follows from this exposition that much remains to be explained as regards the causative agent. That asthma is a neurosis of the cortical centers due to a toxemia, as has been supported by Todd,[35] Lloyd, Bree,[36] and Bretonneau, is very probable and I myself am quite willing to admit this view; but the nature of this toxemia can merely be a matter of speculation. Two years ago I put forward the hypothesis,[37] which, by the way, seems to be substantiated by clinical observations of some medical men (G. Gauthier, Carnot,[38] and Osborn) that disturbances *of the internal secretion of certain glandular organs or of the pulmonary glands might be the cause of this toxemia.* The process is probably either closely related to or identical with Graves-Basedow's disease, which is generally believed to be due to a toxin acting on the nervous system on account of some disorders of the thyroid glands. It is a matter of fact that internal secretion may excite or arrest tissue activities even without the influence of the central nervous system. There can be little doubt that the lungs are avenues for the excretion of unknown poisons. This view becomes more clear when we consider the particular elements or structures in the membrane of the lungs. At first in man and in all the higher animals the mucous glands of the bronchi are in abundance (Kölliker),[39] and it is a curious circumstance that we have no knowledge of the fate of their secretion. It is generally believed that the mucous secretion merely serves as a surface lubricant, but I venture to submit that this view is open to question; in the first place it may be asked not only why the glands are abundant, but also why does the mucin which they secrete differ in certain respects from the mucin secreted by the mucous glands in other situations (Bonne,[40] Müller, Hammersten)?

Again, according to a number of observations carried out by Auld,[41] it was found that these glands were relatively more abundant in the young and seemed gradually to decrease as age advanced. This would seem to imply that they are specifically

related to the growth and development of the lungs. It appears therefore not unreasonable to consider that the mucous glands possess vital functions like hormones not yet apprehended by means of which they maintain or promote a healthy metabolism in the parts in which they are situated, or it is quite possible that they possess an internal secretion, pneumonic hormone, which has a great influence upon the centers of respiration or that their internal secretion may separate and destroy effete products or ptomaines stored up in the blood. That the secretion possesses a substance powerful enough to reduce Fehling's solution seems, at any rate, to favor the latter supposition. We can now easily assume that these undestroyed effete products acting upon the cortical centers leave behind some impression which does not disappear on account of a congenital abnormality of the internal secretion of some glands (probably the bronchial glands), but remains latent for a certain time; there is an accumulation of injuries and when this has reached a certain magnitude some apparently unimportant peculiar factor causes an unburdening or explosion, *i.e.*, an "attack." The alteration of the cortical respiratory centers is then the essential starting point of the asthmatic diathesis. It is a pathological excitability, an abnormal irritability of the imagination, with a corresponding weakness of the will power which is manifested by this respiratory neurosis called asthma.

In such a manner the cortical centers receive certain impressions and utilize them improperly. This is in many respects similar to epilepsy, migraine, and hysterical convulsions. The injuries which may cause an asthmatic attack are generally conveyed by the paths which act more directly on the respiratory centers and by means of them on the sensory, motor, and secretory nerves of the respiratory tract (vagus, trigeminus, and sympathetic). One fact has been known for a long time and is now well established; it is that nasal anomalies produce disturbances in the respiration rhythm. If asthma-like attacks are superadded, the clinical picture becomes very similar to that seen in essential asthma and the difficulties of distinguishing between the two conditions have puzzled many a diagnostician. Exactly the same thing is observed in disturbances of other organs, especially of the stomach, uterus, etc. Fig. 2 explains very clearly these forms of reflex-asthma.

From a consideration of what has been stated above I believe that idiopathic bronchial asthma is due to a congenital excitability of the cortical respiratory centers, which excitability itself is due to a toxemia depending upon alterations of the internal secretion of certain glands, as defined above. This mechanism is not an impossible one, but indisputable evidence of its actual existence has so far been adduced. However, I myself have known two patients about four years of age who have had a number of what are considered attacks of spasmodic laryngitis, a disease which was supposed at one time to be due to disturbances of the thymus and therefore received the name of thymic asthma. The patients are now about twelve years of age and are suffering from attacks of genuine bronchial asthma. I might quote other cases of this kind if I had anatomical data at my disposal. At all events these two cases must be borne in mind. Nevertheless bronchial asthma is, for the time being, a neurosis of the cortical centers, whatever its nature may be. I do know that the term neurosis merely serves as a cloak to our ignorance. But do we not call thus other diseases which are far from being functional disorders? There is no doubt that in the future, as our horizon broadens and we begin to work on altogether different anatomical and physiological lines much will be added to our knowledge. In support of this theory there may be cited the well-known experiments of Weichardt and Besche,[42] among others, who, with injections of different forms of albumin (horse serum), have been able to demonstrate the fact that essential bronchial asthma in a majority of cases is a manifestation of a local cellular anaphylaxis of the lungs. The treatment of bronchial asthma with serum[43] and the very instructive observations of Landerer and Schittenhelm that patients had asthmatic attacks whenever they were injected with horse serum strengthens the hypothesis of a local cellular anaphylaxis. Recently some articles have been published, especially in German, on this subject which seem to corroborate this, my view.[44]

THE NEGRO AND HIS HEALTH PROBLEMS.*

By J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

The negro problem is one of anthropology, not of ethics, religion or variegated opinions. It does involve grave sub-problems of humanity, economics, and common sense. Under no circumstances should it be complicated by emotion. The whole race problem, in the final count, resolves itself into what is to become of the members of an alien people transported, by force and suddenly, to an unsuitable, a hostile environment.

Members of this alien race deserve the same consideration as those of any other: no more, no less. They will get it, and all the more readily if partizanship, unreflecting zeal and politics can be kept upon a rational level. Prejudices for and against the negro neutralize each other. They only serve to obscure fundamental issues, producing no good, but only loss of vitality and moral tone in those who entertain them.

The question for solution resolves itself into *whether members of a tropical race, evolved through thousands of years in hot countries, whose characteristics have gradually become adapted to local climatic conditions, are capable of flourishing or even surviving in a climate wholly at variance with the circumstances of their racial adaptations.*† If the answer is in the affirmative then is opened a host of doubts as to the validity of all experience, history and the findings of anthropologic science; also complex questions arise as to what will become of the race till time, the greatest solver of problems, shall reveal. If the query above proposed is answered in the negative we should at once consider what can be done to effect a transference of the negroes to a suitable habitat.

Two or more races brought into intimate contact socially and domestically evolve hybrids. All experience shows that hybrids, the product of sexual union of antithetic races, such as the white and the black, are inferior to the original stock physically and morally. It is demonstrated by well-attested facts that these hybrids of black and white are vastly more susceptible to certain infections; their moral as well as physical stamina is lower than that of either original race. Undoubtedly there are individual exceptions.

Hybridism lowers normal defenses to degenerative diseases, hence inhibition, the fundamental safeguard, is lessened and degenerative processes then proceed with increasingly rapid strides as the alien blood weakens and the stronger influences prevail. In America the supply of the original negro blood is limited; no new infusions are to be expected.

Meanwhile, pure streams of our Anglo-Saxon, Slavic, Celtic and other blood, infused as they are in the United States with a different, but not largely variant, group of Latins, Hebrews, and others, are polluted by the negroid blood. However, those who feel alarm at this fact can take comfort from the reflection that it is contrary to all precedent for a tropic race (so entirely unfit to subsist in a cold climate like ours) to survive more than ten, or at most fifteen, generations. Our subtropical summers may prolong survival more or less.

Education for the negro during emancipation days and long thereafter was slow to receive adequate attention. Race prejudice took on almost unbelievable phases, among which was opposition by the Southern whites to providing adequate opportunities for equivalent education.

Slowly but surely these difficulties are being adjusted. It is a splendid testimony to the inherent good sense of the negro, to his capacities for swift regeneration, that the chief impetus for education (after General Armstrong pointed the way) arose among, and is sustained by, his own people. They are learning, too, that the form and character of this education must be specialized, simplified, along lines of primitive needs, industrial and agricultural. The fundamental requisite is the inculcation of laws of right living, the basis of which is the mutual sharing of responsibilities provided by family life. Domestic hygiene once taught in the schools promptly and radically regenerates that of the household.

Since the manumitted slave is essentially a bankrupt, without capital, all he has to exchange for a livelihood is his ability to work.

In this work he begins as a mere assistant in production, but may then attain to any height of endeavor for which the individual is fitted or on which he is capable of specializing.

Physical fitness is the *sine qua non* to comfortable as well as useful existence. The problem of health of such an individual is thereupon demonstrated to be paramount.

No line of endeavor is capable of accomplishing so much as one which furnishes opportunities to the wage-earner for learning how to maintain personal health at a maximum.

This one central thought must be kept in mind by all who endeavor to solve health problems of the negro. No race which has evolved slowly and acquired definite physical characteristics can be trans-

*Read at the annual meeting of the American Climalogical Society, Hartford, Conn., June 11, 1912.

†Another important anthropological problem is whether a people practically in or near a state of savagery can be expected to become civilized or conform to civilized standards within the short space of a few hundred years. This, however, is not germane to the present inquiry.

planted suddenly to wholly alien conditions, climatic or other, and adjust themselves to these new and trying conditions, except through a period sufficiently long and by slow evolution.

The negro is an essential part of the body politic. Health problems of the Afro-American stand close to those of all other citizens.

Ten million human beings, differing in racial characteristics, yet closely interwoven with others socially and domestically, demand critical observation. While valuable aids, they are also serious menaces. During the period of enslavement physical conditions were vastly better. There is so much evidence nowadays of deterioration among negroes, induced by the effects of unaccustomed freedom, that the question of their betterment constitutes a vital part of national economics.*

Throughout the length and breadth of our Southern States, and to a lesser degree elsewhere, negroes constitute a large ethnic factor. Among them are splendid personalities, yet the majority lack elements of stability, of dependableness. They are too often their own worst enemies, deficient in fixity of purpose, in judgment, in those reliable characteristics which fit them for citizenship. Intellectually and morally they resemble children. When, unfornately, they became a political issue, endless complications arose. Scholastic opinions circulated by ignorant, often venal, meddlers, insisting upon vague altruistic plans, created a chaos on which too little practical light has as yet been shed. Forces are now at work which may solve the more urgent perplexities.

The negro is too often a creature of impulse, of emotion, of shallow impressionability, and swayed overmuch by mere physical promptings. He is a good imitator, which constitutes a valuable equipment for certain kinds of usefulness. Along with these adolescent qualities there are frequently to be found individuals of keen intelligence, good moral perception, faithfulness to friends, and of deeply religious feeling.

When unmarred by damaging environment, illusage or vitiating influences, the negro is a far more reliable citizen than are some Europeans. It will be generally admitted by those not steeped in prejudices that the unspoiled negro is ofttimes a most estimable, lovable person. The vitiated negro is, however, a peculiarly uncertain, explosive and dangerous creature. It is safe to assume that had the process of emancipation progressed more slowly along the lines of intelligently guided evolution the negro population would now constitute a more valuable group of citizens. Unfortunately he became a political bone of contention and was suddenly projected unprepared as an equal upon society from the position of an hereditary dependent, unprovided with knowledge or training for the next social phase, viz., that of a free and responsible factor in the Commonwealth. The confusion into which he was forced by the period of Reconstruction (the product of a devastating war waged largely in his behalf) created many complications making for physical decrepitude.

Accustomed for generations to dependency, to serf-like conditions, to paternal harboring; or, on the other hand, subjected to occasional cruel, reasonless injustice, there is little wonder that one so constituted fell promptly under the sway of evil influences, of temptations, became often licentious, brutal, or savagely retroactionary. The mischief-making, self-seeking "carpet-bagger" found in him a tool ready to his hand; and "rum, rapine, and rebellion ran riot." Industries were then paralyzed, reorganization was slow and imperfect, the whole local social fabric suffered, the burdens falling heavy enough upon all, but most crushingly on the crude, plastic, unformed negroid element.

To-day a deplorable condition of affairs prevails among these alien racial elements of the community. Many of our duties to them are not yet adequately defined, nor are the factors yet precisely determinable. All will become plain as prejudices on both sides subside and self-seeking politics finally gives way to statesmanship. The solution can only be by patient, tolerant compromises, always utilizing the principles of critical science and true Christianity to guide our decisions.

Solution of the health problems of the negro would seem to be particularly significant and urgent, so intimately interwoven are they with the industrial. The most obvious need is for education of the young in principles of citizenship. No remedy can exceed in value implanting the seeds of self-respect, of industry, of responsibility, of obedience to constituted authority. The most urgent measure is for legislators to control the sale and distribution of delirifacient poisons. Bad as the vitiated negro is, he is an angel of light in his original state compared to any negro crazed by alcohol, cocaine or morphia.

This is the one insistent factor that for the moment overwhelms and obscures all others. Remove or reduce to determinable limitations the accessibility to narcotics and the residue can be dealt with by reasonable means. In establishing punitive measures against free access to alcohol and narcotics some innocent persons will doubtless suffer with the guilty, *i.e.* a few free-born whites may be deprived of their Heaven-sent privilege of going to Hades in the fashion of their choice. This indirect "injustice" or "evil," if such it be, can be endured if only adequate restrictive legislation shall be ultimately secured and enforced.

The proposition would seem thus placed directly up to the voter and the legislator.

Under slavery the health of the negro was peculiarly good, well in advance of the rest of the community. Tuberculosis was then practically unknown among the blacks. In comparing their status then and now something may be conceded to the whole group of aggravating conditions then prevailing, compounded of ignorance, defective instincts, laziness, improvidence, morbid optimism, effects of poverty and the like. All these factors, however, are, at their worst, little things compared to mental and moral vitiation through the destructive effects of narcotic poisons. These bear heavily on collateral health problems; *e.g.* susceptibility to tuberculosis, whereto the negroes are shown to be now three times as liable as the whites.*

Are we now as a nation prepared to deal efficiently with these obviously crucial, though deeply intrenched abuses? How can the paramount significance of his proposition be brought to the consciousness of our citizens?

The negro of the rural sections of the South is now, according to the evidence, in a far better con-

*I myself was a slave-owner, living in boyhood on a plantation. My having then and now much to do with the black peoples may qualify me to express more accurate and just opinions than those who have had no such actual experience.

*See "Tuberculosis in the Negro," by Seale Harris, M.D.

dition of health and morals than the negro of the cities. My personal observation is at the present time chiefly of the urban colored population, far north of their normal habitat. Here a deplorable state exists, part of which is due to natural causes, chiefly climatic. It is far worse than among those races which, through generations of selection and specialization, have become adjusted to urban confinement and restraint. Especially is this true of the Hebrews, who by long evolution have acquired relative immunity to many infections, and resistance to the effects of depressing influences. It will require no less than many centuries for the negro to become adjusted to cold climates. He is unfit racially to flourish above the latitude of Mason and Dixon's Line. All those who know the facts urge that the negro shall never attempt to remain above the line of the Carolinas. Unless the negro is endowed with inherent potentialities radically different from those of all other tropical races, he will deteriorate and perish in cold climates. Just as the Northern races, like the Goths and Vandals, who conquered Southern Europe, deteriorated and disappeared in a few generations, so will any weaker race from the hot South disappear in the North.

The negro is essentially a creature fitted to dwell in wide spaces under the vault of heaven. He must have access to the sun. He is not to be expected, at least not for many generations, to labor so regularly or so continually as one less recently in a savage state. Good work he can do; but those who know him well are aware that the incentives to do his best are not the same as for the Hebrew, the Celt, Slav, German or Italian. Long monotony, confinement, deprivation of normal solaces to his semi-savage spirit induce gloom, revolt, explosions of retroactive impulses. He needs praise, kindly encouragement, personal solicitude and direction, and will then often surpass himself. Fortunately, he is growing ambitious to copy the best in the methods of those about him, and will succeed, provided he is aided by wise, firm and kindly guidance. The negro has become more or less of a political power and it is fortunate that in his views, opinions and decisions his guides are usually the clergy of his own race. It is fortunate that these colored pastors are, in the main, good men, clear-sighted, aware of the gravity of their position, their unique power. Many of them seem fortified by dignity, self-respect, and conscientiousness. They exhibit a deeper interest in the personal welfare, and especially the mental and moral training of their flocks than do those of many other religious bodies. The danger is that too many of them are not men of broad views, with minds above mere financial considerations in the administration of church economics. They are often insufficiently alive to physical or hygienic needs, especially ventilation, temperance and wholesome living. My personal experience with certain of these pastors is most disappointing. They exhibit a degree of narrowness, of selfishness, greatly to be deplored. It is almost impossible to impress some of them with their paramount duty to advise their congregations to seek the country, especially the warm countries, where alone they are racially fitted to flourish—even to survive. Fortunately there is now a large and growing body of negro physicians, dentists and pharmacists.*

*There recently met in Baltimore a national association of these professions, with a membership of three hundred, and two thousand colored men are practising medicine and the allied professions in the United States. Much may be expected from these educated and enlightened persons which will redound to the essential betterment of the race.

It is obviously through education in right feeling, thinking, and doing that any considerable advances can be effected in the ultimate evolution of the black race. The basis of this advance is to encourage in all ways wholesome instincts; to make the integrity of the family the point of departure for all effort, all rewards.

Purity of race is always of paramount value. Hybridism leads to all sorts and degrees of constitutional vitiation. Autochthony is an important condition of racial advance. Before freedom the negro was a chattel, and whether the progeny was white or black, it was equally utilizable. The admixture of a highly cultivated white male with the more simply organized black female produced then a superior article of commerce, a greater promise of available capacity in the product.

The autochthony of the black race is better assured since freedom, because marital alliances can now be at least more stable. Marriage with whites is rare and forms a negligible ethnic factor. This state of familial stability is to be welcomed and if assured it will make for racial betterment.

Hybrids are of proverbially low resisting power to morbific agencies, physical and psychical. This is particularly true of the mulatto and other grades of negroid admixture. The pure blood negro holds the mulatto in deep contempt.

The negro is essentially domestic, and while by no means so conscientious in sexual matters as some races, often exhibits commendable capabilities for faithfulness.*

Vagrant tendencies were exaggerated "before the war" by divers causes, the chief of which was the power of the owner to dispose of slaves diversely.

All over the South schools and colleges for the negro are being established, most of them through the initial impulses emanating from Hampton, Fiske, and Tuskegee. Also far-seeing, benevolent men and women of the North are giving of their time, strength, and means to this incomparable object.

*An important observation made by several Southern physicians is to the effect that sexual lawlessness, resulting in lynchings, is to be explained thus: The male negro is nearly always infected with gonorrhea. He neglects treatment habitually. Chronic prostatic irritation ensues. Thus sexual impulses frequently become overmastering. Alcohol particularly inflames this state and likewise dethrones reason; hence the first female he meets he is tempted to assault. This if often a white female; thereupon the fury and vengeance of white men are excited and disastrous results follow to the negro.

DERAILED FORCES.

By MARGARET A. CLEAVES, M.D.,
NEW YORK.

Not long since the Twentieth Century Limited was hurled over an embankment into the river below. The cause, a broken rail. Back of the actual break was a weakened strain in the atomic structure of the iron itself. Derailed forces work havoc; they are always pitiful and to be dreaded.

The women who recently indulged in a window smashing crusade in London, those who have gone on hunger strikes, and those who with untimely mouthings stalk to and fro upon the earth, are the saddest of living derailed forces; they have missed the joy of life. For them its sweetest springs have not flowed. They have not been and are not physi-

ologically environed. In addition there is an inherent flaw in their fundamental structure, as in the atomic structure of the iron. Superposed upon that is a broken physiological rail. Physiologically, or better, unphysiologically, there is a reason for it.

It is never known when the eternal hysteria present in the physiological unit will break forth, as do pent-up volcanic forces. Derailed human forces are as unsafe as these or the engine and train crashing to the river below.

The visualizing eye of the trained and experienced physician, whose fundamental equipment renders him expert in a knowledge of scientific physiological chemistry and psychoanalysis, relentlessly illuminates these evidences of imperfect mental and normal balance. The revelations are as pitiless and self-revealing as time. None of life's illusions are left.

Illusions are essential to the beauty of life. They soften and veil its hideous truths as does the magic atmosphere of the southern seas the volcano's scarred sides. It is a pain to see them swept away, and in their loss not only maturity but youth suffers. But such is the trend of the day.

Psychical manifestations depend upon physical conditions. To have normal mentality the best of physiological life is necessary. Self knowledge, which is essential to the revelation of the true man or woman, comes with time and experience. To some it comes earlier in life than to others; is influenced by inherited strain and physical conditions.

In the germ cell, from which these erratic forces sprang, whether represented by the feminine or masculine half of the physiological unit, there existed a strain or tendency to lack of nerve stability. The untoward expressions to which such organisms are prone are controlled or limited by training and environment.

Nothing stands for more than the discipline and training of the best of early home life. Nothing so surely invites control as nature's fullest physiological expression, but within the environment of a safe anchorage. Naught else has power to bring the same rest, peace and content. But it must be the best of physiological living. In its absence the *needs must* and devotion to duty are the best of safeguards.

Unless supremacy of physical wellbeing can be obtained under ideal conditions, it may be secured at the expense of the best of normal balance. The ego may become too dominant in its ever encouraged supremacy. The question arises, whether there are not such at this moment prominently in the public eye.

When backed by a vigorous, alert, and versatile mentality, such an ego asserts its supremacy by its thirst for power. Once the taste is acquired the appetite becomes insatiable. So long, however, as life remains physiological, the balance wheel maintains control. But let there be the weakened strain as in the atomic structure of the broken rail, and derailment follows. Otherwise, the conscious ego keeps ever in the foreground to the control of the situation. As the time of life approaches when there is need of a physiological readjustment the stronghold of exact moral balance is apt to be shaken. Then it is that the submerged consciousness, or subconscious ego, tends to become actively in evidence. The supremacy of the conscious ego is not maintained in its full vigor.

What are the physiological conditions that tend to this undoing? What influences have been at work to bring the activities of their submerged selves so prominently to the fore in the modern Caesars and the militant suffragettes? Why these volcanic outbursts, these expressions of an erratic force?

Eternal feminism is unquestionably a factor in the militant suffragettes. But while in neither modern nor yet historic Cæsars is it *feminism,* there is the same fundamental influence at work. What has happened? What part do the phenomena as exhibited by nature's physical forces play? Is chemicophysical, life exempt from the influence of volcanic eruptions, earth shakings, cyclonic disturbances, variations in barometric pressure and electrical conditions?

In the latter, as in the purely physical world, these disturbances are most felt where fundamental physical conditions are least stable. The inherited strain or tendency within the germ plasma is the predestining force. Could the ofttimes ludicrous and always pitiful exhibitions of physiological derailment be prevented? What unphysiological conditions tend to these outbursts? Why do these men and women fly their physiologic orbits? Why their disturbed viewpoint, their lack of the sense of proportion, their abnormal mentality and morality? What has occurred to obscure their logical thinking?

Do the revelations of the scientific pyschoanalyst, brutal as the findings of the skilled pathologist, answer these questions?

Instead of modern psychoanalysis primarily, shall we not look to its standard of exactitude, chemistry, and physiological chemistry especially, for the truth? The fundamental truth must be sought in its revelations.

Activity is essential to being. The organism with its myriads of chemical cells is forever seething in the malestrom of chemical activity. The process of brain thinking bears the most intimate relation to and is influenced by the processes of secreting and excreting. Whatever interferes with the normal secretory and excretory functions interferes with the intellect's supremacy.

The results are most marked and disastrous in unstable organizations, especially at the time of physiological readjustment. It is then that judgment becomes biased, while poise trembles in the balance, or is hopelessly lost.

Karin Michaelis has written of the dangerous age in women. She might have equally well written of the dangerous age in the physiological unit. Its expressions are modified in the masculine half by reason of life's training, of his habits, and environment. That she has not represented the mass, nor yet the best of women, does not gainsay the truth underlying her theme. The physiological conditions at the bottom of all this unrest and turmoil is actively to the front with suffragettes, militant and nonmilitant. Among the ardent campfollowers are younger women to whom fruition is unknown and for whom a physiological balancing of life's strongest instincts is not established. Living under conditions where life's fullness is repressed, or fails of its physiologic expression, they follow the lead of maturity which, for the time at least, can only be regarded as a derailed force. In these that perfect balance, or poise, which tells of life's full fruition does not exist.

The years which exact the heaviest toll are from the fourth to the fifth decade. The greater vitality of individuals with the intensity of modern life

tends to its extension well into the fifth decade. In exceptional instances the sixth decade is reached before full physiological readjustment, with consequent self-understanding and poise, is established. While this should not be an age more dangerous to women than to men, it is by reason of their imperfectly expressed lives and environing conditions.

The lives of women as a rule are full of feeling and emotion rather than purposeful thought and effort. Repressed thoughts, feelings, desire even, may become as dangerous as the earth's unliberated forces.

"All the joys of life are the joys of creation."

To win the best from life, that perfect controlling balance of the supreme and submerged self, the functions of creation must be met. "To create in the region of the body, or in the region of the mind, is to issue from the prison of the body."

The lives of the erratic forces of whom the militant suffragettes may be taken as a type have somehow failed of their fulfillment. Their bodies enchain their liberty. They are storm tossed and at sea from the turmoil within, nor do they know how to reach that peace and content of mind which is the expression of physiological equilibrium.

Through a constant harking back the impressions made by life's lack of understanding and harmony have become indelibly engraved upon their submerged consciousness. These impressions concern the other half of the physiological unit, man, and are apt to be tinctured with all of a woman's complex feelings toward him—jealousy, suspicion, resentment, anger and hatred, so near of kin to love.

Throughout earlier life these have but momentarily imaged themselves upon the conscious ego. These impressions, however, upon the subconscious mind become fixed and deepened under wrong physiological conditions, until they have the very semblance of truth. So deep and clearcut grows this graving that all sense of its untruth is lost. In it they utterly fail to see an expression of their unphysiological selves; to realize that they are in prison to their bodies. Only a half of the physiological unit, and even when mated, too often mismated. What better can be expected?

Possibly men tend less to conduct evidencing physiological derailment. This should be the case, for their natural tastes, instincts, and passions find normal outlets all along the way. They have many compensatory activities of mind and body. Women lead lives of repression, physical as well as mental. Life fails of its full expression. Physiologically endowed with the ability to create, fruition does not follow upon blossoming. For them the organic joy of life is lost.

Their greater numbers, as well as the frequent necessity of becoming commercial factors, compels the seeking of outlets for their repressed energies. These fail to provide the same stimulus to the chemism of life in this especial regard. Still further, the special activity taken on usually exacts its pound of flesh. The entire chemism of life suffers and the injury is expressed physically, mentally and normally.

In either event, the psychical, with its never-ending and conflicting emotions, is always the controlling force. The activities taken on exact too heavy a toll and the woman ceases to be a physiologic creature.

Her physiological privilege, so intimately connected with her power to continue life, becomes a drain upon her vitality. Through long continued and excessive, or otherwise disordered, function the controlling influence upon her higher brain is lost.

Nature intended that she should have periods of repose or physiological rest. There have been none. At every step nature has been defrauded and foully dealt with. Loss of control supervenes, and with that loss the forces of her subconscious ego, which have an inconceivable emotional range are let loose.

In the case of the militant suffragettes they are turned to window smashing, hunger strikes and outrageous attacks upon men in governmental and municipal power. No true physiological woman would be guilty of such conduct. Nor would these women to the same extent exhibit such loss of control had they but known the pitfalls and dangers awaiting unphysiological lives at this time.

The *x*-ray of science previsions a complete exposé of unphysiological lives. It tells with scientific precision why such as these are cheated of full mental poise. To science it is known that that only comes through the highest physiological living.

Throughout the lives of unphysiological woman, or man, there is a never-ending pose. This is bondage, and bondage is galling. Every living thing craves freedom. Without they strain at cords and flutter at bars helplessly and hopelessly.

To be in prison to one's body is the greatest bondage of all. To fail of life's physiological expression is to never know freedom, to pose always.

The bird who is singing his matin song outside of my window this spring morning is filled with the fullness and joy of life. His song is its instinctive expression, and to it will come the happy answer in his mating. Here there is neither pose nor bondage.

There are occasional women who alone and unaided can take up the larger life as does the man. Do they safely outrage nature? Will there not come a time of reckoning? It is given to but few women to do this, and they only succeed who fix their eyes steadfastly upon the stars. The world never knows the cost to such as these because of their steadfastness, perfect poise and calm outlook. They are not common. To the eyes of the world they seem self-sufficient, yet they are not. No mortal is self-sufficient. If the need for full expression of their physiologic selves be not met and crowned, as is right, woman, whatever their walk in life, are prone to become derailed forces, working havoc and devastation in their uncontrolled and uncontrollable fury. Men are not exempt.

These truths are not realized—especially are they not realized by women—but truth they are none the less. They are more or less disillusioning, according to the cells' heritage.

As maturity approaches the average woman finds lessening opportunity for an expression of herself. She finds it increasingly difficult to dominate the scene, and to both men and women the footlights are dear. The time comes for a physiological readjustment. Nature never intended that this time should be passed in the torment of unphysiological bondage. But too often it is. Unphysiological living has been superposed upon a strain of inherited instability.

The impressions of life's unfortunate experiences and emotions are deeply graven upon the submerged consciousness. At the time of physiological readjustment the actual chemism of life undergoes a change. This involves circulatory changes, ofttimes a poisoned blood stream. The subconscious center

by the loss of circulatory control assumes dominance and sways the woman's higher self. In extreme cases cerebral control not only becomes uncertain but is lost. She is storm tossed by the feelings and emotions of her unphysiologic life, which are actively in evidence, as are sea growths and the flotsam and jetsam of the ocean's surface, activities in the waters of the Saragossa Sea. Life's tidal influence has this effect when life is unphysiologically lived. Judgment is lost and shipwreck imminent.

From infancy up the physiologic unit receives impressions which leave indelible traces. They may when other than physiologic leave scars, which in later life become foci of actual danger. By reason of her too often unsatisfactory relation to life women receive many such impressions. In the fullness of life the image upon the conscious self is but fleeting. Just so sure, however, as the photographer's film registers impressions, whether clear cut or blurred, to which it is exposed, just so sure does the human brain bear indelibly fixed upon its constituent cells the impress of all life's happenings.

Among these are many which are irrelevant to life's harmonious development. They seam and scar as does the volcanic lava. Her woman's nature has been defrauded in her creative relation, which is the very fundament of her being. The chemism of this relation to life has suffered interference.

Moreover, into the dull, deadly level of the average woman's restricted life there comes too little to provide that stimulus of change which invites the best of general cellular activity. Here again the process of brain thinking must be considered in relation to the liver and its secretory function, to kidneys and bowels in their excretory relation. It is far from being all psychic. Matter controls mind. Mind must be so trained and disciplined as to minimize this control. In that way man becomes supreme and godlike.

But this attainment previsions the best of ultimate cellular changes with normal secretory and excretory functions. Individual opinion as to the merits of the case in so far as suffrage is concerned has no place here. In their less stable emotional control and complexity due to their sex privilege, women are less desirable factors in matters demanding poise and judgment than men. Business training and environement are not without effect, but the bloom suffers impairment.

Ideal physiological life would minimize the danger, but man's work precludes the physiological living for women. Could women live as did our mothers, grandmothers, meeting life's physiological expression to the full, there would be less of unrest, dissatisfaction and clamor for notoriety. Could her pose be that of the Roman matron, Cornelia, in the midst of nature's jewelled setting, her children, instead of that of a physiological cheat and defaulter, there would not come at life's maturity the expressions of an outraged nature, with its unsatisfied longings and desires. There would not be the constant desire and effort to still hold the center of the stage and dominate the scene.

However, the ideal life has been and still is being lived by many women. The fault lies not alone with the feminine half of the physiological unit. Man fails of the best. He, too, fails in his understanding and appreciation of life's full physiological meaning. His energies are misspent—wasted. Responsibilities which should be his are evaded. Personally he does not suffer as does the woman. But suffer he does. The degree depends upon the inherited strain and the extent of unphysiological living. To man as well as to woman, in their hour of physiological readjustment comes in greater or less degree pain, conflict and physiological peril.

In the modern Cæsar, as well as in the illustrative type of woman, the solar plexus fails of full inhibitory power. At that time *his* dominant traits are revealed in varying degrees of crystallization.

Do the brains of these dominating forces, with their inherited strain of nerve instabilty, express the best of cerebral physiology? Did Cæsar's? Is the moral fiber not deficient? Cassius' inquiry was more than pertinent when he asked, "Upon what meat doth this, Our Cæsar, feed, that he is grown so great?" But the superb crystallization of knowledge and experience embodied in this really scientific query sprang from the same brain that tersely epitomized, "The life of all's in the blood."

Modern scientific research and methods substantiate both question and statement. What influence is at work other than that of physiological readjustment that tends to capitulation of the moral force? What has so disturbed the chemism of life tending to the removal of its supporting bulwarks? Is it fundamentally mind or matter?

Maturity seeks compensation in the pleasures of the table. The habits of eating and drinking become less abstemious even than in early life. The chemistry of assimilation and disassimilation, of which life has exacted tribute all along the way, departs more and more from the normal. Irritation of its terminal fibers are reflected to the center of this inhibiting force, the solar plexus, or abdominal brain. Normal circulatory control suffers impairment.

Toxic stimuli comes from within the body as well as from without; they may act under the right conditions as an organic stimulus; under wrong the toxic effect becomes paramount. The ultimate chemism of life in all its complexity of relation because of sex is not yet understood, nor its rationale explained.

It is shown, however, by observation and experience that the nerve disturbances directly traceable to the influence of sex are comparable clinically with the phenomena of intoxication and abstinence resulting from the introduction of pleasure producing substances, as represented by the alkaloids of certain drugs.

In both instances use may easily become abuse and all the phenomena of disordered nerve states ensue.

Excitability, uncontrollable fury, depression, exhaustion, even follow. Nothing suffers more surely from this unbalanced and poisoned circulation than the moral fiber.

Is it not deficient in the modern Cæsars; likewise in the militant suffragettes?

The tendency to inherited instability counts for much in both of these illustrative types. Whether this strain exists or not, the modern as well as the historic Cæsars are born with a thirst and hunger for power, dominance and supremacy.

Were not such dominant forces born, worlds would not be conquered, poles discovered, thought transmitted wirelessly, scientific truths revealed, tremendous industries built up and colossal fortunes made. The strain is as inherent in their ancestral cells as that inherited strain or tendency in the germ plasma of the lion which makes him the king of the beasts and the terror of the jungle.

For the best the inheritance of stability is essential. Otherwise in life's readjustment, as in adolescence, physiological disturbances follow. When these conditions supervene upon a conscious ego of great supremacy, unless the stability of cerebral control is of the best, danger lurks.

Glimpses of the subconscious ego and its workings are not unlike the revelations of the carelessly curtained rear windows of dwellings. Pictures are unconsciously silhouetted which, if the conscious ego retained its supremacy, would never be seen. In the withdrawal of the curtain the subconscious ego too often reveals the mountebank, not the man, the unphysiological fury, not the physiological woman.

Did Nature intend that mankind should pay this penalty? Should the abdominal brain lose its power of inhibition at the time of physiological readjustment? Was it her intent that men and women should feel resentment at the gliding years?

From a calm, judicial reading of physiological truths, there is but one answer to give to these queries, and that in the negative.

Were life but physiological from ancestral plasma to its every subsequent chemicophysical expression and environing condition, the maximum of its fundamental organic joy would be felt, the gliding years would bring their own compensation, and the end eventuate without hideous disillusionment from the rending of Isis' veil.

616 Madison Avenue.

WORRY AS A CAUSE OF ARTERIOSCLEROSIS.

By HERBERT C. CLAPP, M.D.,

BOSTON.

Almost all of the books and essays on this now fashionable disease, in recounting its causes, either entirely omit, or at least barely mention in passing, one which in my experience seems worthy of an exceedingly important place, either as the prime factor or probably far oftener as a very efficient cooperator, namely, *worry*. The etiology of the disease, as generally agreed upon, includes syphilis (which Anders and many others call the "overshadowing factor"), alcoholism (and perhaps excess of tobacco), overeating (especially of meat), excessive muscular strain, gout, rheumatism, Bright's disease, lead poisoning, hereditary influence, and some toxin or infection. While each one of these is undoubtedly often very effective, either singly or in combination, yet I certainly have met with not a few cases where apparently most, if not all, of these causes had been absent or relatively infrequent, and where worry in a marked degree had been present, especially in certain business or professional men of sedentary life, whose moral habits had always been exemplary.

One notable advantage to be derived from the recognition of worry as a prominent cause is that we thus become more able to avoid the imputation of casting reflection on a person's character. When a man has an attack of angina pectoris or of dilated heart with all the dropsical accompaniments, or of cerebral apoplexy, or of gangrene of the extremities, all of which may result from a so-called hardening of the arteries in different parts of the body, it is neither nice nor pleasant, and it is very often exceedingly unjust to add to his manifold discomforts by casting some suspicion on his morals. This suspicion may occasionally be inferred, even if not designedly or openly expressed, and it will be unfortunate if the idea becomes as prevalent among the laity as it is now among a portion of the medical profession. As to the causation of some diseases of an entirely different kind, we are partially justified in forming a snap judgment without knowing anything about the particulars of the individual case. For instance, so large a majority of the men who are afflicted with locomotor ataxia have previously had syphilis that a guess that a particular individual had strayed from the path of virtue, based entirely on his having this disease, might not be very far from the truth. Again, the sight of a hunchback, no matter how healthy, immediately suggests a previous spinal tuberculosis. Likewise, certain well-known pits or permanent depressed cicatrices on the face are interpreted by everybody as undisputed evidence of a former smallpox. This method of drawing an inference, however, is not at all applicable in arteriosclerosis. Its causes are so various, so indefinite, and often so composite, that any guess must be entirely out of place, and the question is often not easy to decide even with abundant information before us.

If obliged to select any one cause as commoner than another, instead of syphilis I should choose overeating, especially if associated with a sedentary life. In these days of prosperity, advanced civilization, and high tension overeating is exceedingly common; and since the experiments of Professor Chittenden, Horace Fletcher, and others we are realizing more than ever that most of us eat more than is necessary. Lord Bacon wisely said: "The virtue of prosperity is temperance," which many good people interpret as referring only to abstinence from intoxicating liquors. Conscious that they have not the fault of alcoholic intemperance, they complacently fold about themselves the garment of self satisfaction, and continue to indulge in the well formed habit of gormandizing. Caterers say that teetotalers as a rule eat much more than nonabstainers. It would be well if the numerous temperance organizations should begin to consider the advisability of making an important part of their campaign against overeating as well as against drinking. This overfilling of the human furnace with more fuel than it can thoroughly burn up, if sufficiently prolonged, is generally bound to have its effect on the walls of the arteries at some time or other, perhaps only after the lapse of many years. The interval is often so long during which nothing startling has happened, that the consequential nature of the disease when it does come is often not recognized. Indeed, hardening of the arteries is not infrequently considered as one of the customary and proper accompaniments of a ripe old age, or at least of middle life, like the natural process of decay in the leaves of a tree in the fall. That this is not universally true, even at fourscore years, has been proved many times by autopsies on old people, notably on the world-famous Thomas Parr, who died at the advanced age of 152, and whose arteries were found by Harvey on examination after death to be perfectly sound. In fact, there is some reason to believe that if our people lived a perfectly proper and correct hygienic life in every sense, that is, if they were paragons, there would be little heard of arteriosclerosis, and much of that little would be based on the faults of their ancestors, handed down perhaps even four or five generations. Human nature being as it is, the principal reason that old people have this arterial

trouble oftener than the young is because they are greater "sinners" and for a longer time, during which they have not corrected their bad but not necessarily immoral habits, a very long continuance of which is necessary for the production of the affection. Within certain limits the arteries are not diseased because they are old, but they are old because they are diseased. Of course there ultimately comes a time, sooner for some and later for others, when, like everything else, they will wear out with the best of use; but we naturally want to postpone this time as much as possible. One of our purveyors of milk forcibly advertises buttermilk on his wagons with the slogan "Drink buttermilk and live forever." Perhaps even Metchinhoff would not advise us to take this too literally. Query: Did Adam, who lived 930 years; Seth, 912 years; Enos, 905 years; Jared, 962 years; Methusaleh, 969 years; Noah, 950 years, and some of those other worthy gentlemen of olden times, drink buttermilk?

Overeating is a relative term, and most fat people come honestly by their fat. The pleasures of the table are too much for them. Now and then, however, a fat person is really and truly a small eater, as a thin person may be a large eater. The activity and completeness of the processes of digestion, assimilation, and metabolism differ tremendously in different men and women. Fat people are supposed to be jolly (which is not always true), and cheerfulness is certainly a wonderful aid to good digestion. Such a person, with a sufficiency of physical exercise, may digest and assimilate as much food as a person of average size; but if he eats more than this he probably will have a surplus of which he is unable properly to dispose. The rationale of the effect of overeating in this connection in persons of any weight is well known to physicians, and concerns both the quantity and quality of the food. In these cases the blood vessels are constantly overfilled and the blood pressure is therefore increased in them. Increased blood pressure is supposed to be one of the principal immediate agencies in the production of arteriosclerosis. Again, the intestines being overworked by the surplus of food which they are unable properly to handle, toxins are therein generated, which by their absorption cause autointoxication. These toxins not only affect directly the tissue cells of the arterial walls by inducing an irritation that results in a loss of elasticity and degeneration, constituting an arteriosclerosis, but they also affect them in a similar way indirectly through the medium of the vasomotor system, over which they have a powerful influence.

Overeating is liable to produce these unpleasant results in a person even if he is habitually jolly. Ten times more will it do so if he is given to worry. Constant worry takes a powerful hold on the nervous system. Nothing is more effective in inducing neurasthenia. Romberg says: "Neurasthenia is a cause of arteriosclerosis, because of frequent alternations of blood pressure occasioned by the unstable and excitable nervous state." Neurasthenia is also one of the most fruitful causes of intestinal indigestion and its consequent autointoxication, even independently of overeating. Autointoxication, in its turn, besides directly producing arteriosclerosis, tends to produce more neurasthenia by poisoning the nervous system, and a vicious circle is thus established. So the "good" work may go on like the operations of a battledore and shuttlecock, and the poor victim is on the high road toward future trouble with his arteries. This method of reasoning is to me a pretty convincing argument that worry in connection with overeating may have a powerful additional influence in causing arteriosclerosis.

The fact that sooner or later the arteries feel the wear and tear of life is well expressed by Osler in "Modern Medicine," as follows: "Among organs the blood vessels alone enjoy no rest. Not only does a ceaseless rush of fluid pass through them at a speed of ten feet a second, but the walls of the main pipe are subjected to a distending force of 2 1/5 pounds to a square inch 60 to 80 times a minute; 80,000 to 100,000 times in the 24 hours. The heart has rest in diastole, but, distended by the charge from the left ventricle, the arteries pass it on, partly by the natural elasticity of their walls, partly by an active contraction of their muscular fibres. Like other organs, they live under three great laws—use maintains and in a measure sustains structure; overuse leads to degeneration; in time they grow old, in threescore or in fourscore years the limit of their endurance is reached, and they wear out. The stability of tubing of any sort depends on the structure and on the sort of material used, and so it is with the human tubing. With a poor variety of elastic and muscular fibres in the blood vessels, some are unable to resist the wear and tear of everyday life and have, at 40 years of age, arteries as old as those of others at 60."

Excessive muscular strain, long continued, by obstructing the peripheral circulation and thus inducing increased blood pressure, is universally admitted to be a fruitful cause of degeneration of the arteries. Everybody knows that most laboring men, compelled to work constantly and to excess long, weary hours, get old before their time. Much more is this the case, I am sure, if to this overwork is added the effect of worry and other depressing emotions. How often we see such men at fifty, or even less, laid on the shelf and supported by their children, thinking that they have already outlived their usefulness? How often do we read newspaper accounts of accident or death (most likely written by reporters of twenty), wherein the victim, fifty years old, is spoken of as the "aged man"? And this when we ourselves are sure that people in some other walks in life, more happily placed, retain their vigor and faculties for many, many more years. "A man is as old as his arteries." "Use maintains, overuse leads to degeneration."

Likewise we can easily believe that excessive mental work may lead to arterial degeneration. And here I want to protest against the silly delusion which many good people have that no amount of hard mental work ever hurts anybody. This statement, if questioned, is apt to be so hedged about with limitations, such as providing there is sleep enough and food enough, etc., that its force is practically almost emasculated. School teachers especially resort to this statement, perhaps in order to stimulate their lazy pupils. If any breakdown occurs, the teacher does not like to admit that it is from too much study, but lays all the blame on dances, parties and social dissipation, which, of course, are not to be disregarded, if they enter into the question. This is not always the case.

Now we know that people differ tremendously in their ability to work their brains; and that what is overwork for one is child's play for another; and that we all have our limitations beyond which

we cannot go with safety, no matter how many hygienic influences we put around ourselves; so that we must admit that at least some of us, and probably most of us, whether we actually do so or not, can injure ourselves by an excess of pure and unadulterated brain work, even if we faithfully try otherwise not to break nature's laws. From this mental overwork alone comes a certain amount of the wear and tear of life, which knocks the elasticity out of our arteries as well as out of our steps (if it lasts long enough), and which makes us prematurely old. This is true for most of us, and it is no just criticism to instance on othe other side a few men like Gladstone, of enormous powers of endurance, both mental and physical. In fairness to the other side, however, we are forced to admit that much of what is called mental overwork is not so at all, but only a moderate or proper amount of work, plus worry or other depressing emotions. The old proverb that "worry kills more than hard work" is universally admitted to be true, and very often the men that worry thus kills die with hardened arteries. They are often among our most honored and valued citizens, and are cut off before their time by more or less intense application to business mixed with the natural worry and anxiety which our modern strenuous competition and the desire to get rich quickly seem almost to make necessary, especially in neurotics or in persons of nervous temperament. Without this terrible worry in most cases they might readily stand the work. With the worry they are apt to be exhausted by sleepless nights, a great consumer of the bodily energies, by neurasthenia, and by interference with the proper function of their nutritive or trophic nerves in relation to the tissues of the arterial coats. Their worry also easily induces the oncoming of gout, rheumatism, Bright's disease, diabetes, etc., which facilitate the advancing arterial degeneration, especially if they have a hereditary weak streak in that direction. Such men, in such dilemmas, are strongly tempted to overstimulate with alcohol. If they were anxious for any assistance in helping them along the unhappy road on which they were already speeding they could not do better than apply to this agency. In such cases, if they die, is it not really at bottom the worry that kills?

It is well known that in autopsies performed in hospitals for the insane arteriosclerosis is a very common finding; and it goes without saying that worry as a clinical symptom is found in such places with the greatest frequency. This may not prove but strongly suggests the etiological relationship of worry to arteriosclerosis.

In fact, is the proof much more scientific as to the other causes which were enumerated at the beginning of this paper, and which are now pretty generally accepted? Beginning with syphilis, recent reports of examinations of Egyptian mummies show a great deal of arteriosclerosis, fully as much as we have now, and yet in those early times syphilis was supposed to be unknown. How could it be at that time "an overshadowing factor," even if it is now? Again, as to alcohol, it has lately been argued that if this is such a common cause, autopsies in hospitals for inebriates ought to disclose a great deal of the disease; whereas, an examination of the records of one such hospital recently showed an amount at least no more than the average. As to meat eating, certain British observers in India, where very little meat is used, have reported quite as much arteriosclerosis as among European people; and yet from clinical observation we have good reason to believe that all of these, as well as some other causes, are efficient. A few mummies or one small inebriate hospital do not afford statistics on a large enough scale.

Some in skepticism will naturally turn to the vast army of worriers in this world of tears, and will ask why it is that they do not all develop arteriosclerosis, if it is such a potent cause. Thirty years ago, when Koch discovered the tubercle bacillus, and we learned of the millions of germs of tuberculosis seemingly omnipresent, a similar problem confronted us about that disease. The answer then lay as now, in the receptivity of the system, in the condition of the soil. One great help toward the solution of that problem, as in this, came from the analogy of scarlet fever. Why is it that half the people in the world never have the latter disease, in spite of frequent exposure? To be sure, arteriosclerosis is not a germ disease, but the question hinges to a great extent on the quality of material in the arteries given to each of us by heredity, and our manner of living. Some people have such poor stuff in them that it is easily overwhelmed. Some can stand almost anything. Comparatively little tobacco will induce in one man a tobacco heart, whereas another may use large quantities of it, and live happily to an age of 105 years. A garden rubber hose pipe of one quality may quickly succumb to the low pressure of Boston's water works, while that of another quality may stand up bravely against the much higher pressure of the Brookline system. The buildings of the Massachusetts State Sanatorium at Rutland are covered on the outside with plaster. That on the first set of buildings had little by little all dropped off within perhaps three years, and had to be renewed. That on the second set after perhaps ten years is apparently as good as when put on. The first contained proportionately less Portland cement and more sand; sand is cheaper than cement.

To learn the disastrous effects of worry in many other directions one has only to read that famous book by Tuke "On the Influence of the Mind on the Body," also Saleeby's "Worry," Walton's "Why Worry?" and many others. Everyone believes abstractly that worry is a bad thing. The worrier himself hates it as the drunkard hates his drink, and he often makes it worse by worrying because he does worry. He sometimes successfully conceals his anxiety, and thus escapes our notice as a worrier. Many who are old enough can easily remember the intensely funny songs (one of which was the "Wooden Leg") and the other side-splitting comicalities of that prince of entertainers, H. C. Barnabee. And yet between times he was often one of the most miserable of men, way down in the depths of despondency. So, in figuring out the relationship of worry to arteriosclerosis, especially statistically, such cases (and they are numerous) should be taken into consideration. Of course, everybody admits that worry and the other depressing emotions often give rise to functional disease. The only question is, whether or not this can ultimately develop into an organic disease. While this proposition should not be accepted too lightly, because functional disturbances of different kinds are frequently seen extending over very long periods of time without being followed by this change, yet I think our experience entitles us to admit that it does occur if prolonged sufficiently,

and with enough intensity. This is no more strange than that different ways of thinking and different emotions, if continued long enough, may so impress themselves on the features of a person that his character, vicious or noble, impure or pure, irritable or beneficent, may permanently be engraved there, and may be read in them as in a book. So on the present subject, we must agree with Forchheimer, when he says, "excessive functional use of the blood vessels always produces loss of elasticity."

If we find anybody worrying unduly, what shall we do about it? Simply tell him not to do so? This will do just about as much good as Mrs. Partington's arresting the ocean tide with a mop. The proper management of such cases is sometimes more difficult even than the task of installing worry as a cause, and needs separate and special consideration. Worry is exceedingly foolish from many standpoints, and is often indulged in without an adequate basis. The *Boston Globe* wisely prints very often at the head of its editorial columns the following sentence: "I am an old man, and have had many troubles, but most of them never happened." Physicians are said to worry more about their prospects of having arteriosclerosis than other people: a bad habit; it should be given up.

A TENTATIVE DIAGNOSIS OF ANEURYSM OF THE HEPATIC ARTERY, AND FINDINGS AT OPERATION.

By G. A. FRIEDMAN, M.D.,

NEW YORK.

ATTENDING PHYSICIAN IN DIGESTIVE DISEASES VANDERBILT CLINIC; CHIEF IN INTERNAL MEDICINE MOUNT SINAI DISPENSARY.

Aneurysm of the hepatic artery has been looked upon as a pathological finding, giving no clear symptoms and discoverable at autopsy only. Kehr's case of a patient in whom gallstones were believed to have caused the various symptoms present and in whom aneurysm of the hepatic artery was found at operation brought the condition into the realm of diagnostic possibilities and therapeutic interference; in his case Kehr ligated the hepatic artery.

The case I have observed presents several features of interest and shows that we must keep in mind pathological changes in the hepatic artery as the possible cause of symptoms and signs referred by the patient to the upper right hypochondrium.

My patient was a married woman, 35 years old, native of Hungary, who was referred to me at the Mount Sinai Dispensary by Dr. Paul J. Bauerberg of Yonkers, N. Y., on February 2, 1912. She had four living children; had had no miscarriages. Her menstrual periods were somewhat irregular, especially in the last six months; menses lasted but one day, and the dark color of the menstrual blood alarmed her not a little. No history or signs of syphilis were present. Patient denied any excessive use of alcoholic beverages, but later remembered that from her fifth to her fourteenth year she was frequently playing about or helping her father, who was a wine maker. During the whole of each month of October in these years she was encouraged in drinking much wine of his making, this wine being given her by her father as a stimulus in work. In other months of the year she drank wine only occasionally. She used coffee moderately, tea in excess, but of weak "brew." In her childhood she had measles and since has had two attacks of pneumonia. After one childbirth she had much uterine hemorrhage and for this was curetted.

Her present illness she dates back to two years ago, when she had a great deal of worry and grief over the loss of an eye sustained by one of her children. She became very nervous, was always ailing with many indefinite symptoms. Six months before she came to the dispensary she began to have violent attacks of pain in the abdomen, accompanied by chilly sensations. The pain was gnawing in character, lasted for a few minutes, but came on several times daily every few days. Pain began in the right upper abdomen and radiated to the back (right side), right shoulder, and right arm, the pain in the arm never going below the elbow. There was no relation between attacks of pain and the meals. The pain was worse when she was lying down and was relieved by the erect position. She could bring on the pain by talking loudly or by taking several deep breaths. Lately, she had more than usual pain on the day of her menstruation. During the last three months attacks of pain occurred almost daily. Her husband said that she always carried her right hand pressed to the upper right part of the abdomen, as if suffering from constant pain in this situation.

With the increase in frequency of the attacks she began to suffer from a throbbing sensation in the right side of the abdomen. This throbbing and the pain disturbed her sleep, and as a consequence she began to suffer from headaches. She vomited but once in the whole course of her illness; she never noticed fresh blood in her stools; never had tarry movements; had some loss of appetite, but no other dyspeptic symptoms. She was always somewhat irregular in her bowel movements, and lately has been constipated. She was never jaundiced. She claims to have lost 33 pounds in weight.

She was treated by "electricity," apparently by the galvanic current, for nervousness and "neuralgia." One week before she saw me she went to a hospital in town during an attack of pain; the admitting physician diagnosed gallstones and advised immediate operation, to which, however, she did not consent.

Abstracts from repeated physical examinations: Patient fairly well nourished. Face rather flushed, especially during attacks of pain. No jaundice, no subicteric tint of conjunctivæ. On several occasions internal jugular veins on both sides of the neck showed marked pulsation. The peripheral arteries did not seem sclerotic. There was no asthenia, and no loss of weight during the period of observation.

A marked pulsation, for the most part not expansile, was visible in the right hypochondrium. A systolic sound was heard with the pulsation and was transmitted upward to the right chest as far as the third intercostal space. A systolic shock was felt under the costal margin somewhat to the left of the gall-bladder region. While the fingers were pressed over this region a double shock could sometimes be felt in the region of the tenth, eleventh, and twelfth ribs in the scapular line. The liver border was definitely felt two fingers' breadth below the costal margin; it appeared rounded. The pain was increased by palpation high in the right hypochondrium. Subjectively, the pain was not always strictly localized to the right hypochondrium. When palpating high up in the hypochondrium

*Discussed in presentation of the patient at the clinical conference, Mount Sinai Hospital, February 29, 1912.

there occurred radiations of pain to the back and almost always to the right shoulder. Many times after such a manifestation a severe paroxysm of pain was elicited. When the pain came on spontaneously such radiation was not constant. The gall-bladder, spleen, and kidneys were not felt. There were tender spots in the right axillary line, also near the spine, corresponding to the eleventh rib, and hyperesthesia of the skin over the back. There was no tenderness of the bones of the spinal column, nor of the ribs. Heart and lungs normal. Pulse from 70 to 80.

Knee jerks somewhat exaggerated, especially on the left side. The blood-pressure of the patient, which was taken many times at the dispensary and later at the hospital, ranged between 140 and 155 in the brachial arteries, and from 175 to 180 in the dorsales pedis (the patient's thighs were very large). Only on one occasion, on the day she had her menstrual period, the blood-pressure in the brachials was 120.

The eyes were examined by Dr. Mark Schoenberg, who reported nothing abnormal. Pupils reacted to light and accommodation. Refraction media, normal. Optic disc and retina, arteries and veins normal.

Urine was negative on several examinations. No occult blood in the feces.

Wassermann (Dr. Kaliski) negative. Two x-ray pictures negative (Dr. L. Jaches).

Blood: Hemoglobin, 82 per cent.; white cells, 11,200; polymorphonuclear cells, 76 per cent.; lymphocytes, 22 per cent.; eosinophiles, 2 per cent.

Temperature twice taken at the dispensary: 99.8° and 99.2°.

At the hospital, when she was admitted on February 16, 1912 (service of Dr. Julius Rudish), and where she stayed for two weeks, her temperature reached once a maximum of 100°.

The examination of stomach contents on fasting did not show any macroscopical or microscopical stagnation; and after an Ewald test breakfast free HCl was absent once, on another occasion present: no lactic acid.

Gynecological examination negative.

A high division of the aorta into the iliac arteries was discovered at the hospital.

Epicrisis.—We had before us a woman of 35, who gave a history of measles and pneumonia and of excessive use of alcohol for a month each year in childhood. She had worried a great deal because of a serious accident to her son and 18 months after this had occurred she began to have violent paroxysmal pain in the right upper quadrant of her abdomen. The pain was sharp, shooting in character, and increased by the recumbent position. There was visible pulsation over the liver, occasionally expansile; this was accompanied by a systolic shock felt under the ribs. A throbbing sensation appeared later when the attacks of pain had become more frequent. The lower border of the liver was palpable and rounded.

What diagnosis should have been considered in this case?

Gallstones, of course, were first thought of, as the patient has had four childbirths, one followed by hemorrhage and curettage. But jaundice was completely absent, the attacks of pain were very frequent, the pain lasted a few minutes only and was never severe enough to call for morphine. Sensation of throbbing came on with increase in frequency of the painful paroxysms. The visible pulsation over the liver did not fit the diagnosis of gallstones.

Duodenal ulcer was suspected because of pain and tenderness in the right parasternal line in the region of the umbilicus. But there was no blood in the feces; the attacks of pain had no relation to meals; the pain was never relieved by assuming the recumbent position, but even increased by it.

Malignant disease of the liver did not seem probable. There were no symptoms of an original growth elsewhere, and primary disease of the organ would have led to marked enlargement. There was no cachexia; no loss of weight while under observation.

Neuralgia was thought of, and in the presence of a herpes zoster, intercostal and brachial neuralgia, there could have been a slight probability, tender spots and radiation to the arm speaking for such a diagnosis. Starr points out that marked pulsation of the vessels is met with in neuralgia. But there was some enlargement of the liver, and treatment for neuralgia (electricity) together with time should have had some effect upon the condition.

Caries was excluded by absence of tenderness over the ribs and vertebræ.

Hepatalgia or "nervous liver colic" was also considered. I have never been convinced in my own observations of the reality of this condition, yet the possibility has been mentioned by other writers, seven cases having been described by Pariser. Such colic may be easily confounded with gallstone colic, paroxysms of pain in right hypochondrium continuing from a few minutes to four hours. In women such attacks of pain are dependent upon menstruation. The liver may be tender at the time. No icterus and no inflammatory condition of any nature is discoverable. Such attacks are usually met with in neurasthenic or hysterical subjects and are very obstinate to treatment.

In our case the liver was tender and its border definitely palpable. Though the pain was here intense during menstrual periods, the constant pulsation and the throbbing sensation spoke for a more real condition than "neuralgia of the liver." Moreover, our patient was not a neurotic or an hysterical woman, exhibiting only such nervous symptoms as any sufferer from a chronic painful affection may have.

Visceral arteriosclerosis was next considered. The pain in this condition, known as arteriosclerotic colic, is excruciating in character, especially if the aorta or the superior mesenteric artery is involved, such structures as the lower part of the duodenum, the small, and a portion of the large intestine being affected. The mesenteric artery being an "end artery," these structures suffer very much from diminished supply of blood. In our patient, the pain has been intense, but not of the atrocious character described by Ortner. Moreover, disturbances of digestion were quite absent, and sclerosis of inferior mesenteric or gastric arteries could thus be excluded.

The pulsation in our patient was never a "venous pulse"; moreover, the heart was normal, no tricuspid regurgitation being present. Portal cirrhosis is said to be sometimes responsible for a venous pulsation, but our patient had no signs of cirrhosis, no swelling of the limbs, no enlarged spleen, and no ascites. The pulse in the jugular veins which was occasionally seen was of physiological nature. Moreover, a systolic blow accompanied the liver pulsation. The high division of the

aorta could not have been responsible for the pulsation; it is a congenital condition and should have made itself felt before the age of 35, if at all. Moreover, such pulsation would hardly be as palpable to the right of the midline and audible as high up as the third right intercostal space. Of course, if gallstone colic was not excluded, we could think of a possible pulsation of a gall-bladder from the transmitted pulsation of the aorta. But we felt a systolic shock in the region of the portal fissure and to the left of the gall-bladder, and did not see the necessity of supposing that two conditions were present to cause the symptoms. Moreover, the rounded liver border spoke for some pathological change in the liver itself.

Aneurysm of the aorta was excluded by negative *x*-ray plates and by the high-blood pressure in the dorsalis pedis as compared with the radial pressure. Moreover, the palpable liver and its changed border were to be explained.

An arterial liver pulse is met with in many conditions; for example, in aortic regurgitation and in certain inflammatory conditions leading to hyperemia of the liver. Sahli saw such a pulse in a patient with cholangitis. Ramskill saw liver pulsation in a case of encephaloid carcinoma, which simulated aneurysm. Mere pulsation of the liver could not be used as a sign of aneurysm, but in our patient we had many other factors to think of, viz.: (1) Paroxysms of pain of neuralgic type; (2) an inconstant sensation of throbbing, appearing after the attacks of pain have been experienced for some time; (3) arterial liver pulse; (4) a comparative high blood-pressure at an age when such pressure, especially in the female, should not be expected; (5) alcoholism in childhood; (6) long continued worry and grief over an accident to the patient's son.

We, therefore, made a tentative diagnosis of aneurysm of hepatic artery and referred the patient with this diagnosis to the Mount Sinai Hospital.

Our reasoning was as follows: Other conditions explaining the symptoms could be excluded. A definite history of abuse of alcohol in childhood was obtainable and we could assume a sclerosis of the hepatic artery in consequence of it. Unusual wear and tear of life was present in our patient, because of the acute and long continued worry and grief over her child's misfortune. Arteriosclerosis, as we know, is frequently an expression of the damage done by long continued psychic strain. The first attacks of pain could be explained by pressure of the dilated artery upon the hepatic nerve plexus, situated in the portal fissure. This plexus is a branch of the celiac and the latter is connected with the brachial through the phrenic nerve and its branches.

This could explain the radiation of pain to the right shoulder and right arm. Jaundice was absent, because the bile ducts were not pressed upon, and the absence of pressure upon the hepatic vein explained the absence of ascites. The sensation of throbbing and the visible pulsation over the liver were, of course, directly due to the dilated artery.

The patient left the hospital after a stay of two weeks, having refused an operation. During the next month her symptoms became more severe and she finally re-entered for an exploratory laparotomy which was performed by Dr. Arpad Gerster on April 9, 1912. The following is his report of the operative findings:

"As soon as the margin of the lesser omentum was exposed, the hepatic artery became visible as a pulsating cylindrical body, having the diameter of a large goosequill. It formed a loop with its convexity downward. Its proximal continuation could be distinctly followed by palpation of the celiac axis, this portion forming a large loop with its convexity pointing upward, so that the whole vessel, as far as visible and palpable, represented a large Roman "S," its entire estimated length being six inches. A marked whirl could be felt on the gentlest contact with the vessel. The gall-bladder was normal, moderately distended with bile, easily expressed into the common duct. The common duct was not distended and contained no stones, no palpable tumor, no cicatricial ulcer; absence of stone in the gall-bladder.

"All the exposed structures, especially the duodenum, showed marked cyanosis, charged to the bad anesthesia. The margin of the liver was markedly rounded and thickened, free from cicatrices. The stomach was much dilated by gases which were withdrawn with a tube. The index finger could be easily invaginated into the pylorus.

"The division of the aorta into the iliacs, instead of corresponding to fourth, corresponded to the second lumbar vertebra. The calibre of the aorta and iliacs and the coronaries of the stomach was normal.

"*Diagnosis.*—Dilatation and elongation of the hepatic artery. No aneurysm."

I must, however, insist that in my opinion the findings at the operation justified the diagnosis "aneurysm" rather than merely elongation and dilatation of the artery, as Dr. Gerster has put it.

Post factum, no one can doubt that the paroxysms of neuralgic pain in our patient, the throbbing sensation, and the visible pulsation over the liver were due to the condition of the hepatic artery. Now this condition was discovered to be an elongation and dilatation, and only in a vulgar sense could such condition be differentiated from aneurysm, which usually brings to mind a larger or smaller round or oval swelling in the course of an artery. However, in the beginning, every aneurysm must consist simply of dilatation and perhaps of elongation of an artery and only later assume the more localized form of a rounded swelling, as the weakened wall of the vessel gives way more and more.

Kaufmann, speaking of aneurysms, states the following: "The consequence of arteriosclerosis can be a dilatation (aneurysm) of the arteries, especially of such without firm neighboring tissue. The arcus aortæ will be most frequently dilated, small arteries (lienalis, coronariæ cordis, temporalis) usually becoming dilated and lengthened."

In another place Kaufmann says: "Dilatation of an artery, also called arteriectasia, may be diffuse or circumscribed. Some authors call only the latter aneurysm, but this is an error: there are transitions between the two forms."

Perhaps the best analogy is found in our conception of a tumor which usually implies a swelling. Yet, many a cancer begins at a flat plaque and perhaps diminishes the volume of the part at the outset, because of contraction. However, such tissue is "tumor," even though only much later it may show a real swelling or increase of volume in the tissue affected. Certainly a few strands of cancer tissue found in the beginning of a malignant disease of the breast form a malignant tumor of the breast, as much as when the breast becomes double

its normal size from overgrowth of normal tissue. The characteristic of tumor is not found in its size, but in type and rôle of tissue contained in it, and the same, of course, is true of aneurysm. A sclerosed, dilated, and elongated artery is an aneurysm—perhaps an incipient one, but nevertheless an aneurysm as much as the large sac found in later stages of an aortic disease of this nature.

I, therefore, present the above case as the first example of an aneurysm (dilatation and elongation) of hepatic artery diagnosed before operation.

AMENORRHEA DUE TO THYROID INSUFFICIENCY.

By PETER K. OLITSKY, M.D.,
NEW YORK.
ASSISTANT ADJUNCT GYNECOLOGIST, HAR MORIAH HOSPITAL.

Medical literature has been burdened from the earliest times with numerous theories regarding the cause that induces menstruation. It was thought to be a process incident to woman's supposed uncleanliness; or that it was a process of eliminating effete matter; or that it was akin to venesection in ridding a plethoric person of her superfluous blood.

Later attention was centered in the relation of the ovary to menstruation. Strassmann claimed that increased pressure in the ovary brought on the flow. He injected sterile fluid into the ovary and the animal, as a result, began rutting. Pflüger held that the presence of a ripe follicle reflexly induced menstruation. Lowenthal maintained that the flux depended on non-fertilization of the ovum, comparable to a primitive abortion. A great many observers, on the other hand, have shown that ovulation is independent of menstruation. More recently the internal secretion of the ovary has been held to be responsible for the induction of the menses. Görl (*Münchener medizinische Wochenschrift*, LVIII, No. 30) concludes that the internal secretion of the ovary first appears at puberty and that it leads to the development of the secondary sexual characteristics; at the time of the maturation of an ovum this secretion is changed chemically, which in turn induces menstruation.

What stimulates that ovary to act? To say that the thyroid does would be conforming to the consensus of modern opinions. That the thyroid secretion acts as a hormone was first demonstrated by Sajous (*New York Medical Journal*, XCIV, No. 30). He showed that all phosphorus-laden cells are sensitized by the thyroid. Porter (*Surgery, Gynecology, and Obstetrics*, XIII, No. 6) calls the thyroid a "sex organ"; all of us have noted the enlargement of the thyroid during menstruation. Leopold Levi and de Rothschild ("Endocrinologie," 1911) and Collard-Huard in her Paris Thèse (1910-1911) have clearly demonstrated the interdependence of the thyroid, the ovary, and menstruation.

Hence, it stands to reason that a temporary or permanent insufficiency of the thyroid secretion would produce a diminution of hormone to the ovary; the ovary is then not stimulated, and amenorrhea results.

This is illustrated in the following typical case: Patient, Y. W., 24, appeared in the dispensary of the Har Moriah Hospital in November, 1911. Her family history is negative. She began to menstruate when 13, and menstruation has always been regular, of six days' duration, with a profuse loss of blood. She has been married five years. One year after marriage a child was born. One year later she aborted a three-months fetus. She has not been living with her husband for the past year.

When the patient first presented herself to our notice she complained of frequent and "burning" urination. On examination urethral caruncles were found. These were excised, only to return in several weeks. In January she "missed" her period. Also in February and in March, 1912. Pelvic examination disclosed a normal uterus and adnexa. A complement fixation test was negative. Examination of the urine was negative. Urethral and cervical smears showed no gonococci. A blood count disclosed a slight anemia. Her blood pressure (systolic) was 108 mm. Hg.

At this time (March) she appeared as if she had added twenty-five pounds to her weight. She was large and clumsy; eyelids were puffy; eyes heavy; skin dry, and her mentality dulled somewhat. Her thyroid was not palpable; the other organs were normal. Thyroid extract was ordered. By mistake she took 30 grains per diem instead of 15 grains for three days without any untoward result. At the end of a week there was a slight menstrual show for a day; in another week corresponding to her menstrual period she had a scanty flow. The thyroid dose was diminished to 5 grains per diem and she has had several normal menses since. At the same time she has lost about ten pounds in weight and has felt much better as regards her headaches and backaches.

It is apparent that patients suffering from amenorrhea, which is evidently not due to organic disturbances, should be given the benefit of thyroid therapy.

My thanks are due to Drs. Vineberg and Bodenheimer for permission to report this case.

ARE THE PRESENT METHODS OF DISPOSAL OF HUMAN EXCREMENT SATISFACTORY?

By ISAAC W. BREWER, M.D.,
ITHACA, N. Y.

Probably the majority of the people of this country would answer "yes" to this question. They might add that some improvement could be made in the methods in vogue in rural communities, but with few exceptions they would be satisfied with the methods used in the cities. However, a more careful study of the subject does not leave one in such a contented frame of mind. It is not intended in

this paper to go into the mechanical operation or the cost of any systems but rather to look at the question from a somewhat broader standpoint than we usually do, considering it from the ideal sanitary and economical points, trusting that this statement may stimulate others to work out a better system than we now have.

To be satisfactory the method adopted must fulfil the following requirements: (1) It must remove the excreta from the homes of human beings promptly. (2) It must not create a nuisance or a breeding place for flies or mosquitoes. (3) It must be economical. (4) It must conserve all of the fertilizer in the excreta and return it to the soil for the nourishment of plant life. (5) It must not pollute the water or food supplies of human beings or animals.

The methods now employed may be classified as follows: (1) Water carriage, with or without purification. (2) Privies. (3) Cesspools. (4) Pails. (5) Dry earth closets.

1. The water carriage system has been in use for about 100 years, and has been improved each year until it now appears most satisfactory. It is objectionable because of the pollution of rivers, lakes, and other water courses that it causes. If combined with purification, it is costly and generally all of the fertilizer is lost. If used for irrigation however some of the fertilizer can be saved. Irrigation plants rarely pay except where water is scarce. The mixing of excrement with water is costly, and the sewers entail an immense outlay of capital. Each time a closet is flushed about 5 gallons of water is used. Each person will use the toilet at least three times daily which means 15 gallons of water per person per day. This quantity costs a large amount of money in a city of the size of New York.

2. Privies are far too common in this country. They fulfil none of the requirements which we have stated and are open to every objection that could be raised against any system. They are the breeding place for millions of flies which scatter the germs from feces far and wide. They are also the homes of countless mosquitoes.

3. Cesspools are open to most of the objections urged against privies and should not be tolerated in any community.

4. Pails are rarely used in the United States, but are common in tropical countries and have been installed in some places in the Philippines. They can be operated so as to create no nuisance and to fulfil some of the requirements we have stated. In practice they are objectionable in the home, and the scavenger generally slops them over the ground whenever he removes them. Their contents are available for fertilizer, but in this country there is a general objection to the use of raw feces for fertilizer.

5. Dry earth closets, as operated at present, are very undesirable, being malodorous and liable to pollute the place where installed as well as the point where they are emptied. Their success depends upon the cooperation of every member of the household, which is difficult to obtain. Owing to the carelessness of the scavenger the dumping place becomes polluted and the breeding place of flies. They are better, however, than pails, privies, or cesspools. They are the best means we have of conserving the fertilizer, and if properly managed the pathogenic germs in the feces soon are killed off.

The method of disposal used on trains is a disgrace to the country. The closets in the ordinary coaches are generally unclean and the hoppers through which the feces are discharged are always filthy. They distribute the feces along the tracks and are undoubtedly a means of dissemination of typhoid fever, dysentery, and similar diseases. I know one reservoir through which a trunkline runs. One could imagine what would happen if a patient suffering from cholera were to use the toilet while crossing it.

The same is true of boats. The toilet facilities are generally better and cleaner, but they, too, distribute the germs of disease over a large area.

Mr. James J. Hill has said that within fifty years our country will not be able to support its population. In his argument he shows that the average yield of wheat per acre is about fourteen bushels. He further states that with improved methods of agriculture the yield could be increased to twenty-eight bushels per acre and that we would still be able to export food products.

In China and Japan, where the population is very dense, none of the excrement of animals or human beings is wasted. While no one would advocate the Chinese or Japanese methods in handling feces and urine, we would advocate an improvement on these methods that would rid them of their objectionable features and at the same time save the fertilizer. It is within the probability that such a system can be devised that will fully meet the requirements of sanitation and at the same time the economic requirements.

122 Eddy Street.

Arrhythmia in Healthy Children.—R. Friberger notes that arrhythmia is present in all children between the ages of five and fourteen years, and at this period of life is to be regarded as physiological. Neither the varying degree of bodily development, nor a slight amount of cardiac weakness, nor a lability of the nervous system appears to bear any appreciable relationship to this arrhythmia.—*Archiv für die Kinderheilkunde.*

Pathological Changes in Muscles.—R. C. Jewesbury and W. W. C. Topley have found that in wasting diseases the voluntary muscles show varying degrees of histological change bearing little relation to the actual degree of wasting present. These changes consist of alterations in the size, shape, and staining reactions of the fibers, increase in the fiber nuclei, and alteration in their arrangement, sometimes resulting in the production of false giant cells; and lastly of a relative increase of the interstitial tissue. In acute general diseases muscle changes are extremely slight, consisting of some degree of hyaline and granular change, and in a certain small number of cases of fatty degeneration. Fatty changes: In certain disorders associated with an abnormal carbohydrate metabolism there is a great increase in the amount of interstitial fat present. In many cases small collections of fat droplets are present in the neighborhood of the fiber nuclei; these are common in advanced life, rare in children, and almost entirely absent in animals. They bear no relation to true fatty degeneration, and it is doubtful if they have any pathological significance. True fatty degeneration appears to be much less common than is usually stated, but occurs to a marked degree in cases of diphtheritic toxemia, in certain blood disorders, and in poisoning by phosphorus. Glycogen: Of the many muscles stained for glycogen it was only strikingly present in each of three cases of diabetes examined. Amyloid change was not found in any case examined.—*Proceedings of the Royal Society of Medicine.*

there occurred radiations of pain to the back and almost always to the right shoulder. Many times after such a manifestation a severe paroxysm of pain was elicited. When the pain came on spontaneously such radiation was not constant. The gall-bladder, spleen, and kidneys were not felt. There were tender spots in the right axillary line, also near the spine, corresponding to the eleventh rib, and hyperesthesia of the skin over the back. There was no tenderness of the bones of the spinal column, nor of the ribs. Heart and lungs normal. Pulse from 70 to 80.

Knee jerks somewhat exaggerated, especially on the left side. The blood-pressure of the patient, which was taken many times at the dispensary and later at the hospital, ranged between 140 and 155 in the brachial arteries, and from 175 to 180 in the dorsales pedis (the patient's thighs were very large). Only on one occasion, on the day she had her menstrual period, the blood-pressure in the brachials was 120.

The eyes were examined by Dr. Mark Schoenberg, who reported nothing abnormal. Pupils reacted to light and accommodation. Refraction media, normal. Optic disc and retina, arteries and veins normal.

Urine was negative on several examinations. No occult blood in the feces.

Wassermann (Dr. Kaliski) negative. Two x-ray pictures negative (Dr. L. Jaches).

Blood: Hemoglobin, 82 per cent.; white cells, 11,200; polymorphonuclear cells, 76 per cent.; lymphocytes, 22 per cent.; eosinophiles, 2 per cent.

Temperature twice taken at the dispensary: 99.8° and 99.2°.

At the hospital, when she was admitted on February 16, 1912 (service of Dr. Julius Rudish), and where she stayed for two weeks, her temperature reached once a maximum of 100°.

The examination of stomach contents on fasting did not show any macroscopical or microscopical stagnation; and after an Ewald test breakfast free HCl was absent once, on another occasion present; no lactic acid.

Gynecological examination negative.

A high division of the aorta into the iliac arteries was discovered at the hospital.

Epicrisis.—We had before us a woman of 35, who gave a history of measles and pneumonia and of excessive use of alcohol for a month each year in childhood. She had worried a great deal because of a serious accident to her son and 18 months after this had occurred she began to have violent paroxysmal pain in the right upper quadrant of her abdomen. The pain was sharp, shooting in character, and increased by the recumbent position. There was visible pulsation over the liver, occasionally expansile; this was accompanied by a systolic shock felt under the ribs. A throbbing sensation appeared later when the attacks of pain had become more frequent. The lower border of the liver was palpable and rounded.

What diagnosis should have been considered in this case?

Gallstones, of course, were first thought of, as the patient has had four childbirths, one followed by hemorrhage and curettage. But jaundice was completely absent, the attacks of pain were very frequent, the pain lasted a few minutes only and was never severe enough to call for morphine. Sensation of throbbing came on with increase in frequency of the painful paroxysms. The visible pulsation over the liver did not fit the diagnosis of gallstones.

Duodenal ulcer was suspected because of pain and tenderness in the right parasternal line in the region of the umbilicus. But there was no blood in the feces; the attacks of pain had no relation to meals; the pain was never relieved by assuming the recumbent position, but even increased by it.

Malignant disease of the liver did not seem probable. There were no symptoms of an original growth elsewhere, and primary disease of the organ would have led to marked enlargement. There was no cachexia; no loss of weight while under observation.

Neuralgia was thought of, and in the presence of a herpes zoster, intercostal and brachial neuralgia, there could have been a slight probability, tender spots and radiation to the arm speaking for such a diagnosis. Starr points out that marked pulsation of the vessels is met with in neuralgia. But there was some enlargement of the liver, and treatment for neuralgia (electricity) together with time should have had some effect upon the condition.

Caries was excluded by absence of tenderness over the ribs and vertebræ.

Hepatalgia or "nervous liver colic" was also considered. I have never been convinced in my own observations of the reality of this condition, yet the possibility has been mentioned by other writers, seven cases having been described by Pariser. Such colic may be easily confounded with gallstone colic, paroxysms of pain in right hypochondrium continuing from a few minutes to four hours. In women such attacks of pain are dependent upon menstruation. The liver may be tender at the time. No icterus and no inflammatory condition of any nature is discoverable. Such attacks are usually met with in neurasthenic or hysterical subjects and are very obstinate to treatment.

In our case the liver was tender and its border definitely palpable. Though the pain was here intense during menstrual periods, the constant pulsation and the throbbing sensation spoke for a more real condition than "neuralgia of the liver." Moreover, our patient was not a neurotic or an hysterical woman, exhibiting only such nervous symptoms as any sufferer from a chronic painful affection may have.

Visceral arteriosclerosis was next considered. The pain in this condition, known as arteriosclerotic colic, is excruciating in character, especially if the aorta or the superior mesenteric artery is involved, such structures as the lower part of the duodenum, the small, and a portion of the large intestine being affected. The mesenteric artery being an "end artery," these structures suffer very much from diminished supply of blood. In our patient, the pain has been intense, but not of the atrocious character described by Ortner. Moreover, disturbances of digestion were quite absent, and sclerosis of inferior mesenteric or gastric arteries could thus be excluded.

The pulsation in our patient was never a "venous pulse"; moreover, the heart was normal, no tricuspid regurgitation being present. Portal cirrhosis is said to be sometimes responsible for a venous pulsation, but our patient had no signs of cirrhosis, no swelling of the limbs, no enlarged spleen, and no ascites. The pulse in the jugular veins which was occasionally seen was of physiological nature. Moreover, a systolic blow accompanied the liver pulsation. The high division of the

aorta could not have been responsible for the pulsation; it is a congenital condition and should have made itself felt before the age of 35, if at all. Moreover, such pulsation would hardly be as palpable to the right of the midline and audible as high up as the third right intercostal space. Of course, if gallstone colic was not excluded, we could think of a possible pulsation of a gall-bladder from the transmitted pulsation of the aorta. But we felt a systolic shock in the region of the portal fissure and to the left of the gall-bladder, and did not see the necessity of supposing that two conditions were present to cause the symptoms. Moreover, the rounded liver border spoke for some pathological change in the liver itself.

Aneurysm of the aorta was excluded by negative x-ray plates and by the high-blood pressure in the dorsalis pedis as compared with the radial pressure. Moreover, the palpable liver and its changed border were to be explained.

An arterial liver pulse is met with in many conditions; for example, in aortic regurgitation and in certain inflammatory conditions leading to hyperemia of the liver. Sahli saw such a pulse in a patient with cholangitis. Ramskill saw liver pulsation in a case of encephaloid carcinoma, which simulated aneurysm. Mere pulsation of the liver could not be used as a sign of aneurysm, but in our patient we had many other factors to think of, viz.: (1) Paroxysms of pain of neuralgic type; (2) an inconstant sensation of throbbing, appearing after the attacks of pain have been experienced for some time; (3) arterial liver pulse; (4) a comparative high blood-pressure at an age when such pressure, especially in the female, should not be expected; (5) alcoholism in childhood; (6) long continued worry and grief over an accident to the patient's son.

We, therefore, made a tentative diagnosis of aneurysm of hepatic artery and referred the patient with this diagnosis to the Mount Sinai Hospital.

Our reasoning was as follows: Other conditions explaining the symptoms could be excluded. A definite history of abuse of alcohol in childhood was obtainable and we could assume a sclerosis of the hepatic artery in consequence of it. Unusual wear and tear of life was present in our patient, because of the acute and long continued worry and grief over her child's misfortune. Arteriosclerosis, as we know, is frequently an expression of the damage done by long continued psychic strain. The first attacks of pain could be explained by pressure of the dilated artery upon the hepatic nerve plexus, situated in the portal fissure. This plexus is a branch of the celiac and the latter is connected with the brachial through the phrenic nerve and its branches.

This could explain the radiation of pain to the right shoulder and right arm. Jaundice was absent, because the bile ducts were not pressed upon, and the absence of pressure upon the hepatic vein explained the absence of ascites. The sensation of throbbing and the visible pulsation over the liver were, of course, directly due to the dilated artery.

The patient left the hospital after a stay of two weeks, having refused an operation. During the next month her symptoms became more severe and she finally re-entered for an exploratory laparotomy which was performed by Dr. Arpad Gerster on April 9, 1912. The following is his report of the operative findings:

"As soon as the margin of the lesser omentum was exposed, the hepatic artery became visible as a pulsating cylindrical body, having the diameter of a large goosequill. It formed a loop with its convexity downward. Its proximal continuation could be distinctly followed by palpation of the celiac axis, this portion forming a large loop with its convexity pointing upward, so that the whole vessel, as far as visible and palpable, represented a large Roman "S," its entire estimated length being six inches. A marked whirl could be felt on the gentlest contact with the vessel. The gall-bladder was normal, moderately distended with bile, easily expressed into the common duct. The common duct was not distended and contained no stones, no palpable tumor, no cicatricial ulcer; absence of stone in the gall-bladder.

"All the exposed structures, especially the duodenum, showed marked cyanosis, charged to the bad anesthesia. The margin of the liver was markedly rounded and thickened, free from cicatrices. The stomach was much dilated by gases which were withdrawn with a tube. The index finger could be easily invaginated into the pylorus.

"The division of the aorta into the iliacs, instead of corresponding to fourth, corresponded to the second lumbar vertebra. The calibre of the aorta and iliacs and the coronaries of the stomach was normal.

"*Diagnosis.*—Dilatation and elongation of the hepatic artery. No aneurysm."

I must, however, insist that in my opinion the findings at the operation justified the diagnosis "aneurysm" rather than merely elongation and dilatation of the artery, as Dr. Gerster has put it.

Post factum, no one can doubt that the paroxysms of neuralgic pain in our patient, the throbbing sensation, and the visible pulsation over the liver were due to the condition of the hepatic artery. Now this condition was discovered to be an elongation and dilatation, and only in a vulgar sense could such condition be differentiated from aneurysm, which usually brings to mind a larger or smaller round or oval swelling in the course of an artery. However, in the beginning, every aneurysm must consist simply of dilatation and perhaps of elongation of an artery and only later assume the more localized form of a rounded swelling, as the weakened wall of the vessel gives way more and more.

Kaufmann, speaking of aneurysms, states the following: "The consequence of arteriosclerosis can be a dilatation (aneurysm) of the arteries, especially of such without firm neighboring tissue. The arcus aortæ will be most frequently dilated, small arteries (lienalis, coronariæ cordis, temporalis) usually becoming dilated and lengthened."

In another place Kaufmann says: "Dilatation of an artery, also called arteriectasia, may be diffuse or circumscribed. Some authors call only the latter aneurysm, but this is an error: there are transitions between the two forms."

Perhaps the best analogy is found in our conception of a tumor which usually implies a swelling. Yet, many a cancer begins at a flat plaque and perhaps diminishes the volume of the part at the outset, because of contraction. However, such tissue is "tumor," even though only much later it may show a real swelling or increase of volume in the tissue affected. Certainly a few strands of cancer tissue found in the beginning of a malignant disease of the breast form a malignant tumor of the breast, as much as when the breast becomes double

its normal size from overgrowth of normal tissue. The characteristic of tumor is not found in its size, but in type and rôle of tissue contained in it, and the same, of course, is true of aneurysm. A sclerosed, dilated, and elongated artery is an aneurysm—perhaps an incipient one, but nevertheless an aneurysm as much as the large sac found in later stages of an aortic disease of this nature.

I, therefore, present the above case as the first example of an aneurysm (dilatation and elongation) of hepatic artery diagnosed before operation.

AMENORRHEA DUE TO THYROID INSUFFICIENCY.

By PETER K. OLITSKY, M.D.,

NEW YORK.

ASSISTANT ADJUNCT GYNECOLOGIST, HAR MORIAH HOSPITAL.

Medical literature has been burdened from the earliest times with numerous theories regarding the cause that induces menstruation. It was thought to be a process incident to woman's supposed uncleanliness; or that it was a process of eliminating effete matter; or that it was akin to venesection in ridding a plethoric person of her superfluous blood.

Later attention was centered in the relation of the ovary to menstruation. Strassmann claimed that increased pressure in the ovary brought on the flow. He injected sterile fluid into the ovary and the animal, as a result, began rutting. Pflüger held that the presence of a ripe follicle reflexly induced menstruation. Lowenthal maintained that the flux depended on non-fertilization of the ovum, comparable to a primitive abortion. A great many observers, on the other hand, have shown that ovulation is independent of menstruation. More recently the internal secretion of the ovary has been held to be responsible for the induction of the menses. Görl (*Münchener medizinische Wochenschrift*, LVIII, No. 30) concludes that the internal secretion of the ovary first appears at puberty and that it leads to the development of the secondary sexual characteristics; at the time of the maturation of an ovum this secretion is changed chemically, which in turn induces menstruation.

What stimulates that ovary to act? To say that the thyroid does would be conforming to the consensus of modern opinions. That the thyroid secretion acts as a hormone was first demonstrated by Sajous (*New York Medical Journal*, XCIV, No. 30). He showed that all phosphorus-laden cells are sensitized by the thyroid. Porter (*Surgery, Gynecology, and Obstetrics*, XIII, No. 6) calls the thyroid a "sex organ"; all of us have noted the enlargement of the thyroid during menstruation. Leopold Levi and de Rothschild ("Endocrinologie," 1911) and Collard-Huard in her Paris Thèse (1910-1911) have clearly demonstrated the interdependence of the thyroid, the ovary, and menstruation.

Hence, it stands to reason that a temporary or permanent insufficiency of the thyroid secretion would produce a diminution of hormone to the ovary; the ovary is then not stimulated, and amenorrhea results.

This is illustrated in the following typical case: Patient, Y. W., 24, appeared in the dispensary of the Har Moriah Hospital in November, 1911. Her family history is negative. She began to menstruate when 13, and menstruation has always been regular, of six days' duration, with a profuse loss of blood. She has been married five years. One year after marriage a child was born. One year later she aborted a three-months fetus. She has not been living with her husband for the past year.

When the patient first presented herself to our notice she complained of frequent and "burning" urination. On examination urethral caruncles were found. These were excised, only to return in several weeks. In January she "missed" her period. Also in February and in March, 1912. Pelvic examination disclosed a normal uterus and adnexa. A complement fixation test was negative. Examination of the urine was negative. Urethral and cervical smears showed no gonococci. A blood count disclosed a slight anemia. Her blood pressure (systolic) was 108 mm. Hg.

At this time (March) she appeared as if she had added twenty-five pounds to her weight. She was large and clumsy; eyelids were puffy; eyes heavy; skin dry, and her mentality dulled somewhat. Her thyroid was not palpable; the other organs were normal. Thyroid extract was ordered. By mistake she took 30 grains per diem instead of 15 grains for three days without any untoward result. At the end of a week there was a slight menstrual show for a day; in another week corresponding to her menstrual period she had a scanty flow. The thyroid dose was diminished to 5 grains per diem and she has had several normal menses since. At the same time she has lost about ten pounds in weight and has felt much better as regards her headaches and backaches.

It is apparent that patients suffering from amenorrhea, which is evidently not due to organic disturbances, should be given the benefit of thyroid therapy.

My thanks are due to Drs. Vineberg and Bodenheimer for permission to report this case.

ARE THE PRESENT METHODS OF DISPOSAL OF HUMAN EXCREMENT SATISFACTORY?

By ISAAC W. BREWER, M.D.,

ITHACA, N. Y.

Probably the majority of the people of this country would answer "yes" to this question. They might add that some improvement could be made in the methods in vogue in rural communities, but with few exceptions they would be satisfied with the methods used in the cities. However, a more careful study of the subject does not leave one in such a contented frame of mind. It is not intended in

this paper to go into the mechanical operation or the cost of any systems but rather to look at the question from a somewhat broader standpoint than we usually do, considering it from the ideal sanitary and economical points, trusting that this statement may stimulate others to work out a better system than we now have.

To be satisfactory the method adopted must fulfil the following requirements: (1) It must remove the excreta from the homes of human beings promptly. (2) It must not create a nuisance or a breeding place for flies or mosquitoes. (3) It must be economical. (4) It must conserve all of the fertilizer in the excreta and return it to the soil for the nourishment of plant life. (5) It must not pollute the water or food supplies of human beings or animals.

The methods now employed may be classified as follows: (1) Water carriage, with or without purification. (2) Privies. (3) Cesspools. (4) Pails. (5) Dry earth closets.

1. The water carriage system has been in use for about 100 years, and has been improved each year until it now appears most satisfactory. It is objectionable because of the pollution of rivers, lakes, and other water courses that it causes. If combined with purification, it is costly and generally all of the fertilizer is lost. If used for irrigation however some of the fertilizer can be saved. Irrigation plants rarely pay except where water is scarce. The mixing of excrement with water is costly, and the sewers entail an immense outlay of capital. Each time a closet is flushed about 5 gallons of water is used. Each person will use the toilet at least three times daily which means 15 gallons of water per person per day. This quantity costs a large amount of money in a city of the size of New York.

2. Privies are far too common in this country. They fulfil none of the requirements which we have stated and are open to every objection that could be raised against any system. They are the breeding place for millions of flies which scatter the germs from feces far and wide. They are also the homes of countless mosquitoes.

3. Cesspools are open to most of the objections urged against privies and should not be tolerated in any community.

4. Pails are rarely used in the United States, but are common in tropical countries and have been installed in some places in the Philippines. They can be operated so as to create no nuisance and to fulfil some of the requirements we have stated. In practice they are objectionable in the home, and the scavenger generally slops them over the ground whenever he removes them. Their contents are available for fertilizer, but in this country there is a general objection to the use of raw feces for fertilizer.

5. Dry earth closets, as operated at present, are very undesirable, being malodorous and liable to pollute the place where installed as well as the point where they are emptied. Their success depends upon the cooperation of every member of the household, which is difficult to obtain. Owing to the carelessness of the scavenger the dumping place becomes polluted and the breeding place of flies. They are better, however, than pails, privies, or cesspools. They are the best means we have of conserving the fertilizer, and if properly managed the pathogenic germs in the feces soon are killed off.

The method of disposal used on trains is a disgrace to the country. The closets in the ordinary coaches are generally unclean and the hoppers through which the feces are discharged are always filthy. They distribute the feces along the tracks and are undoubtedly a means of dissemination of typhoid fever, dysentery, and similar diseases. I know one reservoir through which a trunkline runs. One could imagine what would happen if a patient suffering from cholera were to use the toilet while crossing it.

The same is true of boats. The toilet facilities are generally better and cleaner, but they, too, distribute the germs of disease over a large area.

Mr. James J. Hill has said that within fifty years our country will not be able to support its population. In his argument he shows that the average yield of wheat per acre is about fourteen bushels. He further states that with improved methods of agriculture the yield could be increased to twenty-eight bushels per acre and that we would still be able to export food products.

In China and Japan, where the population is very dense, none of the excrement of animals or human beings is wasted. While no one would advocate the Chinese or Japanese methods in handling feces and urine, we would advocate an improvement on these methods that would rid them of their objectionable features and at the same time save the fertilizer. It is within the probability that such a system can be devised that will fully meet the requirements of sanitation and at the same time the economic requirements.

AUTOINTOXICATION IN THE ARMY.

THE *Journal of the Military Service Institution of the United States* awards annually the so-called Seaman prize for the best essay on a subject selected by the founder of the prize, Major L. L. Seaman, and approved by council. The subject for last year was as follows: "How can autointoxication, that rarely recognized disease which has directly or indirectly caused more invalidism and mortality in modern armies than all other pathogenic causes combined, be prevented?" And the prize was awarded to Captain Nathan S. Jarvis, U. S. Army, whose essay on the subject is published in the July-August number of the journal. The subject selected is one that may cause surprise in the mind of the general reader. That such picked men among young adults of the nation as soldiers must necessarily be are sufferers from autointoxication, especially when it is remembered that their diet is for the most part very simple, may indeed be doubted. And Dr. Jarvis properly states at the very outset of his paper that the premise implied in the subject "may be true as a rash guess, but it cannot be proved by the usual methods of deducing medical statistics." He then gives a historical survey of the theory of autointoxication, and summarizes as well the views of such men as Combe, Vaughan and Novy, Fischer, *et al.*

So far as the army is concerned, Jarvis thinks that careful attention to the treatment of slight as well as severe intestinal disease should be insisted upon, because such conditions invite the absorption of poisons from the digestive tract. So far as the diet is concerned, he thinks that that of the American soldier compares favorably with the diet of other armies. However, boiling or cooking all food, is advised so as to insure against chance infection and especially the use of such beverage as weak tea instead of water. Jarvis warns against the dangers of canned provisions, which are safe enough if properly prepared before canning and cooked immediately after being removed from the can, but are a source of various morbid conditions if carelessly packed or kept some time in unsealed receptacles. Of the direct methods of fighting autointoxication Jarvis mentions the usual intestinal antiseptics and the mechanical measures calculated to clear the intestines of putrefactive material or diminish the activity of certain microorganisms.

In acknowledging the careful work of the author in summarizing what is known about autointoxication, we think that the subject, selected presumably as of interest to the great body of army medical men, was a very unfortunate one. This subject has given rise to a prolixity of quasi-scientific literature in the general medical press, has been exploited by promoters of various drugs, modified foods, drugless methods of treatment, etc., until the laity and not a few medical men have been misled into thinking that autointoxication is a clear and easily diagnosed condition, instead of an obscure entity, the very existence of which has been doubted, and proofs of which so far brought forth are certainly not entirely satisfactory. Much loose thinking and purposeless treatment has resulted to the detriment of the profession and patients as well.

The subject needs the light of careful clinical observation and unbiased laboratory work, but such work in the study of autointoxication cannot be done in the army, where the material is least favorable for the development of the condition. We call attention with great pleasure to the much more promising subject for the next award of the prize, the full wording being as follows: How can the Medical Departments of the Army, Navy, and Public Health Service be best utilized for research work in connection with a department of public health? This subject is of more than mere local importance for the army and navy, and the paper awarded the prize will be awaited with interest by the general medical public.

THE TREATMENT OF TETANUS WITH CARBOLIC ACID.

THE enthusiasm which followed the remarkable results obtained by the use of diphtheria antitoxin led the medical profession to believe that in serotherapy was to be found all the promise of future success in the treatment of infectious disease; drugs and other non-biological methods of treatment were for a time scorned by the laboratory enthusiasts. However, it was soon shown that what was possible in diphtheria could not be duplicated in other infections, the mortality of which was not at all affected by various antitoxins however prepared. Vaccines were then brought forward, still in the enthusiastic preference of biological methods of treatment, and for a time these were hailed as the real deliverers of suffering mankind. At the present time, however, the general consensus of opinion is that vaccines hold a subordinate, though quite an actual, place in the therapy of infections. They may be fraught with great possibilities, but our methods of using them have so far given but very modest results.

The enthusiasm over serotherapy was best shown by the great hopes which greeted the production of tetanus antitoxin. For a time it seemed as if this dread disease was to be made quite innocuous, provided antitoxin was used. But soon enough it was shown that, however great its prophylactic value, the tetanus antitoxin possessed no curative value whatever. Now and then a patient treated with it recovered, but usually the case was one of mild

nature with a long period of incubation. The best test of antitoxin was made by the Russians during the late war with Japan, and both the published and private opinions of Russian military surgeons have completely denied it any therapeutic virtue.

Meanwhile, the Italians have been using a very simple method of treatment suggested years ago by Baccelli, and have finally succeeded in attracting the attention elsewhere by the remarkable results obtained. Baccelli's treatment consists in subcutaneous injections of carbolic acid in 3 per cent. dilution, given frequently enough to make the total quantity of pure phenol injected daily equal to from 0.3 to 0.5 c.c. (5 to 7.5 grains). Imperiali, writing in 1910, gives the results obtained in a sufficient number of cases to exclude merely chance results. Of fifteen patients with the foudroyant form of tetanus, only one patient recovered (mortality, 93.3 per cent.); of thirty-nine patients with a very severe form of the disease, twenty-two recovered and seventeen died (mortality, 43.5 per cent.); of ninety-four cases with the usual severe form of the disease, ninety-two recovered and only two died (mortality, 2.12 per cent.). Richter gives the average mortality, with the usual methods of treatment, as 88 per cent.; during the Civil War the mortality among the Federal troops was 92.56 per cent.; and Behring himself grants that the mortality of those treated with antitoxin reached 88 per cent. In a later paper Baccelli gathers one hundred and ninety cases treated by his method, and states that the mortality in these was 17.36 per cent., a figure that about equals the percentage of recoveries among the cases treated with antitoxin and other methods.

The above résumé is gleaned from a paper in the *Russkii Vratch* (Vol. XI, No. 28) by N. A. Goulyaeff, who had gone through the enthusiasm over the use of antitoxin and the subsequent disappointment. Lately, he had a chance to treat two very severe cases of tetanus by the Baccelli method, and to his great surprise both recovered. The first one had an incubation of eight or ten days, and when brought to the hospital was suffering from severe muscular spasms, frequently involving the respiratory muscles. Goulyaeff used 14.5 c.c. of pure phenol in the course of about five weeks in treating this patient, and is convinced that the drug has some actual quantitative relation to the amount of toxin present, for the diminution in the daily quantity injected was several times followed by an increase in the tetanic spasms. The second case was one of "cephalic tetanus" appearing after an incubation of six days. This variety of tetanus has frequently given 100 per cent. mortality. Goulyaeff's patient received 5.4 c.c. of phenol in two weeks and recovered completely. In neither case were any untoward effects noted from the administration of carbolic acid; the urine was carefully followed to note any such effects.

In America the saner methods of celebrating Independence Day have resulted in a marked diminution of cases of tetanus. However, such cases occur not infrequently in every large hospital and in the practice of most surgeons, and Baccelli's method of treatment should certainly be again tried. Not the least thing in its favor is its utter simplicity, which permits its use amid the most inadequate surroundings of any practice.

STATE MEDICAL SERVICE IN GREAT BRITAIN.

In various discussions of the new British insurance scheme it has been pointed out that it is not the principle of the bill to which the medical men of England object, but the obviously unfair manner in which Mr. Lloyd George has proposed to deal with the profession. The pay offered physicians of Great Britain under the insurance scheme was inadequate, and moreover they would be placed in the hands of the approved societies. Nearly all, however, laymen and medical men, are agreed that the objects of the bill are sound and that eventually England must adopt a scheme of this nature. Therefore when it was decided at the recent meeting of the British Medical Association to oppose the bill in its present form, the conclusion was also reached that to be consistent medical men themselves must bring forward an alternative scheme. Otherwise, the supporters of the measure would say, "you have wrecked a plan the principle of which you approve, and have not suggested anything in its place; consequently you must have taken this course impelled by merely selfish motives."

Fortunately, an alternative scheme was proposed at the meeting just over, and from a perusal of the same it appears to be, in its main features, both feasible and reasonable. Dr. Rentoul of Liverpool read a paper at the meeting referred to in which he stated his views as to the initiation of a State medical service. He is one of those who hold that the medical profession is now pledged to the formation of some such service and points out that nationalization of medicine in Great Britain is not so far off as some think. The thin edge of the wedge has been inserted already, for the State now appoints many official physicians, the number of which is increasing daily. Rentoul suggests as the chief points bearing upon a public health service the following: (1) That the insurance committees receive from the Insurance Commissioners a sum of money equal to about $1.50 per insured person per annum, this to be handed quarterly to the doctor of the insured person. (2) That the Insurance Commissioners give 60 cents per annum per member to the doctor or druggist, who agrees to supply the insured person with medicine. Thus 60 cents plus $1.50 would be the minimum sum asked for by the British Medical Association. (3) In order to meet Mr. Lloyd George's objection that he cannot or will not grant the amount asked for per member per annum, Rentoul would suggest that each insured person pay a yearly sum of $1.25, or about two cents weekly, to the doctor. In other words, that they pay the amount the better class friendly societies now pay their doctors. These three sums of $1.50, 60 cents, and $1.25 would, with 14,000,000 insured persons, give the doctors an annual income of about $2,360 each, exclusive of confinements, vaccinations, notifications, operations, sanatoria,

etc., these probably totaling from $250 to $500 each doctor yearly.

Rentoul contends that medical men at the present time give more in charity, principally in gratuitous services, than do the members of any other profession or trade, and that it is time that the public cease to impose upon them. He characterizes as brazen effrontery the suggestion of the Chancellor of the Exchequer that the present income of medical men in Great Britain should be further reduced yearly by $14,000,000. He is also of the opinion that an eight hundred dollar income limit should be adopted, with a sliding scale of income at, say, $300, $400, $500, and $800, the yearly contribution by the insured person to vary with the income.

Attention may be drawn to the fact that German practitioners under their insurance scheme get more by far than is proposed by the British Medical Association. At Leipzig, medical men have been granted $3.75 per annum, while the average German allowance for drugs is about 94 cents. Some form of insurance is sure to come in every European country, and the formation of a National State Medical Service as suggested by Rentoul appears to fit in with the tendency of the times. Conditions in this country so far as the medical profession is concerned are not too rosy. In all the big cities societies and lodges are increasing, and the physician's income is at the same time decreasing. It may not be long ere a scheme for State insurance or nationalization is mooted here, and therefore it is well that physicians of this country should watch the course of events in Europe and endeavor to profit by experience gained there.

INTESTINAL INFANTILISM.

The late Dr. Herter of New York published a small monograph on what he termed "Intestinal Infantilism," which affection he attributed in some manner to the persistence of the intestinal bacterial flora of the nursling period. At a later period Prof. Heubner, who recognized the clinical entity, assigned as its cause a congenital intestinal insufficiency, the presence of the flora thus becoming, we suppose, the effect and not the cause of the condition.

At a recent session of the Charité Hospital Physicians of Berlin (*Berliner klinische Wochenschrift,* August 19) Eckert presented two patients with this form of infantilism. There was a uniform arrest of development dating from an early period of childhood. One child aged 11 years appeared to be seven years younger. The individual finds were numerous and complex. Failure to improve under pancreas therapy seemed to show that the condition was not akin to Bramwell's pancreatic infantilism. Thyroidin was then exhibited with brilliant results as far as amelioration of the symptoms was concerned. Whether the children will start to regain their growth cannot yet be foreshadowed, as the observation period is too brief.

The most striking improvement was seen in the locomotive system. The youngest child, but four years old, had been extremely backward in walking and speech, although there was no actual mental defect. Under thyroidin she began to improve rapidly and was soon running about and talking. As Herter showed, this form of infantilism is attended by severe chronic diarrhea, and this condition responded in part to the treatment.

Viereck's new diagnostic method, based on testing the chromaffin system, was practised. Glucose and adrenalin given simultaneously produced glycosuria, showing abnormal tonus of the sympathetic nerves. Atropin caused tachycardia, pilocarpin was inert. The stigmata of the exudative diathesis and lymphatism were wholly wanting.

The pancreas was plainly in abeyance as hardly any trypsin was poured into the intestine. The author believes that that organ was stimulated indirectly through the thyroid. The thyroid of the patients could not be felt. The infantilism was certainly not myxedematous, although there were a few symptoms in common with myxedema, such as the scanty dry hair.

Paradoxical Diphtheria.

The abnormal course sometimes pursued by individual and family diphtheria was no doubt largely responsible for some of the antagonism shown toward serotherapy, both when the latter was first introduced and also subsequently. We can comprehend this antagonism to-day when the position of serotherapy has become fixed in certain episodes which are reported from time to time. Thus Jess, before the Medical Society of Kiel last June (*Münchener medizinische Wochenschrift,* August 20), stated that he attended a child with lacunar tonsillitis as the clinical diagnosis, the bacteriological examination being negative. Two days later a second child was attacked with clinical diphtheria as the diagnosis aand both children were given serum without waiting for the bacteriological diagnosis, which was later positive for the second child. Both children promptly and uneventfully recovered as far as diphtheria was concerned, but both developed serum disease after recovery, which also ended uneventfully. About one year later, corresponding to the annual recurrence of anginous affections, one of the children again developed what was clinically a lacunar angina without any marked systemic reaction. The condition was persistent and examination showed diphtheria bacilli in pure culture. Fear of anaphylaxis prevented serum injection. The tonsillar patches persisted under vigorous local treatment for several weeks, finally becoming sterile as to diphtheria germs. The sister received no prophylactic injection for fear of anaphylaxis, but contracted nothing. The patient during the more than five weeks of diphtheria had shown only a slight evening rise of temperature as evidence of toxemia. The author also knew of a similar episode and the sole way of explaining these second attacks is that ordinarily both the first attack and the serum injections would have secured a considerable period of immunity, but in these cases neither afforded any protection worth mentioning.

Botryomycosis.

The peculiar raspberry-like formations which sometimes follow wounds of the hands and other exposed localities have probably been regarded by the laity and family practitioner as nothing more

than a special form of "proud flesh." They have also been seen in the horse, and at one period were believed to have been caused by inoculation with an unknown parasite. Inferentially the same causation was attributed to the human form. The attempt to introduce the term botryomycosis into familiar use seems, however, to have been attended with failure. The Germans prefer the term pyogenic or telangiectatic granuloma, and despite the peculiar clinical form the consensus of opinion has attributed the lesion to some unexplained activity of ordinary pyogenic cocci. The most peculiar feature of this lesion, however, is its tendency to recur when removed. At a recent meeting of the Kiel Medical Society (*Berliner klinische Wochenschrift*, August 12) Konjetzny was able to demonstrate two cases of this affection. He was unable to point to any new causal agent to explain its nature, but his histological studies led him to believe that these formations are tumors and not mere granulomata. The abundant new formation of blood vessels and the coincident occurrence of sarcoma-like tissue would apparently show the presence of a proliferating angioma or angiosarcoma. It may have been more than a coincidence that one of these growths developed on the site of a minute vascular birthmark. These tumors of traumatic origin may also have affinities with keloid formations.

News of the Week.

Yellow Fever in Mexico.—A recent report states that yellow fever has been present in Mexico since August 1, 1911. During that time sixty-eight cases with thirty-two deaths were reported in Merida. In San Juan Bautista, in the State of Tabasco, there were between May 4 and August 10 of this year a total of fifty-three cases of the disease with twenty-two deaths. The disease is now reported to be epidemic in Frontera, a port fifty-five miles from San Juan Bautista, having been carried from the latter place by troops transferred to Frontera, and Acting Assistant Surgeon J. F. Eaves has been assigned to temporary duty in the American Consulate at Frontera for the purpose of fumigating vessels and performing other necessary quarantine work on vessels prior to their departure for ports in this country. The disease has also been epidemic during the summer in Chile, and cases have occurred in Brazil, Colombia, Ecuador, and Venezuela. Investigation has shown that in certain localities of South America and on the west coast of Africa, and in Central America and southern Mexico yellow fever is endemic and has become a disease of childhood, the adult natives possessing immunity acquired by infection in early life. These endemic foci are a constant menace to all ports having commercial relations with them.

Smallpox in Pennsylvania.—During the week ending September 13 sixteen deaths from smallpox occurred in Pittsburgh, and on that day thirteen new cases were reported, making a total of 178 cases then in the city. Hundreds of persons are leaving the town, and in some quarters where the streets are roped off and quarantine lines are maintained by mounted police the inhabitants are in a state of panic. City physicians are vaccinating all of the school children, the members of the police force have also been vaccinated, and the street car company has ordered the vaccination of its motormen and conductors. The Health Director of the city is one of those who has contracted the disease. An epidemic of smallpox has also broken out in Carbondale, Pa., more than fifty cases having been reported. The Pennsylvania State Department of Health has taken charge of the situation.

Typhoid Fever at Allentown.—Upward of twenty-five cases of typhoid fever, with at least two deaths, have appeared within a short time in a newly annexed portion of Allentown, Pa. At first it was thought the water supply was at fault, but investigation disclosed the fact that almost all of those attacked received milk from one original source of supply.

Polluted Oysters.—The menace of oysters infected with typhoid germs is the subject of a report recently issued by the United States Department of Agriculture as the result of an investigation into an epidemic of typhoid fever occurring in Goshen, N. Y., in October, 1911. The source of infection in this instance was traced to oysters from Jamaica Bay, the investigator declaring that millions of gallons of sewage were discharged daily into the bay, around and even directly over the oyster beds. The Sanitary Superintendent of New York, however, states that there is no danger of another outbreak, and that, as a matter of fact, the oysters became contaminated, not in the bay itself, but in the freshening grounds further back in the meadows. Following an inspection of the oyster beds made by the New York Department of Health last spring, the small sewers polluting the freshening grounds were destroyed as much as possible. Examination of the water in the bay, it is alleged, shows that there is no danger of contamination because of the immense volume of water and the strong tides. This statement one may be permitted to doubt.

Liner Brings Smallpox.—The Italian SS. *America*, which arrived in New York on September 11 from Naples, was detained at Quarantine because of the presence of a case of virulent smallpox on board. The patient was removed to Hoffman Island together with 574 of the steerage passengers and crew with whom he had come in contact, and the other passengers after vaccination were allowed to land.

Deaths in New York.—During the week ending September 7 there were 1,229 deaths in New York City, the death rate per thousand being 12.39, as compared with 13.24 for the same week of last year, when the total number of deaths was 1,265. Of infants under one year of age there were 319 deaths, 50 less than during the preceding week.

Medical Examinations.—The State Board of Medical Examiners of California announces that of the 200 physicians who took the recent examinations, over 80 per cent. had passed successfully and had been granted licenses to practise.

Deaths of Aviators.—On September 11 Lieut. Siebert, an aerial scout in the German Army maneuvers, was killed by the fall of his aeroplane and his companion was seriously injured. This was the sixth fatal accident in six days among army aviators alone.

Infantile Paralysis.—Reports from Buffalo state that up to September 9 there had occurred in that city within the last few months 220 cases of infantile paralysis, with twenty-six deaths and permanent crippling in 60 per cent. of the survivors. Four new cases were reported on September 8. The disease has also been epidemic in Southern California, and from June 8 to August 17, a total

of 226 cases were reported in Los Angeles, with forty-three deaths.

"Open Window" Class.—In Montclair, N. J., where one of the first open-air schools for delicate children was opened, an "open window" class has been started in the Hillside Grammar School, to be followed by other classes of the same sort as seems desirable.

Radium Supply.—On behalf of the Bank of Radium of Paris and of Madame Curie, arrangements have been made for the purchase of property in Meeker, Col., containing the largest carnotite deposits in this country. The property is being acquired in the hope that radium will be found in sufficient quantities to permit of greater researches by the French scientists. In addition to radium carnotite, which was named in honor of President Carnot of France, contains radium salts, uranium, and vanadium.

Health Department Needs.—The New York City Department of Health has submitted to the Board of Estimate a request for an appropriation for the year 1913 of $4,510,308.25, which is an increase of $1,367,921 or 43.5 per cent. over the amount allowed for the current year. A considerable part of the increase is desired for raising some existing salaries and providing salaries for positions to be created.

For Health Conservation.—At a meeting of prominent Democrats held in the Colony Club, New York, on September 9, a bureau of health conservation in the interest of pure food and the consequent maintenance and improvement of health was formed, with the following officers: *President,* Dr. Harvey W. Wiley of Washington; *Vice-President,* Prof. Irving Fisher of New Haven; *Secretary,* Mrs. J. Borden Harriman of New York; *Permanent Committee,* Dr. J. N. McCormack, Bowling Green, Ky., representing the American Medical Association; Major W. O. Owen of Washington; Dr. Richard C. Newton of Montclair, N. J., and Dr. E. R. L. Gould and Dr. Thomas Darlington of New York. The formation of the bureau is a consequence of the health plank in the Democratic platform.

Gifts to Charities.—By the will of the late John Henry Schaefer of New York the Presbyterian and the German Hospitals of this city receive each a bequest of $10,000.

By the will of the late Mrs. Ida A. Whitman of Philadelphia contingent bequests of $5,000 each are made to the Presbyterian Hospital and the Episcopal Hospital to endow free beds in memory of her husband and a similar bequest of $2,500 to the Children's Hospital.

By the will of the late John G. Hees of Philadelphia the sum of $1,000 is bequeathed to the German Hospital.

By the will of the late Robert Wolf of Philadelphia the sum of $100 is bequeathed to the Jewish Hospital Association.

Fordham Faculty Dinner.—On Thursday evening of last week the Medical Faculty of Fordham University gave a dinner at the Hotel Astor in honor of the foreign lecturers in the International Extension Course on diseases of the nervous system which is being held this month. The guests of honor were Dr. Henry Head and Dr. Gordon Holmes of London and Dr. Nicolas Achucarro of Madrid. Drs. Alwyn Knauer of Munich and Carl Jung of Zurich, the other foreign lecturers in the course, were absent, having not yet arrived from Europe. Among the other guests were many of the most eminent neurologists of the country. The Rev. Dr. Thomas J. McClusky, President of Fordham University, presided, and Dr. James J. Walsh, Dean of the Medical Faculty, acted as toast-master. The speakers were Father McClusky, Father Hanselman, Provincial of the Society of Jesus; Dr. Henry Head, Dr. M. Allen Starr, Dr. Sears of the University of Vermont, Dr. M. J. Lewi, Judge O'Sullivan, and Paul Fuller, Esq., Dean of the Faculty of Law of Fordham University. The keynote of the addresses was internationalism in medical study as exemplified in the international extension course, which had been initiated somewhat in the nature of an experiment and which had from the first proved to be an unqualified success both in attendance and in the interest of the lectures. At the close of the speaking Dr. Maloney, to whom credit was given for originating the course, announced that the next series of lectures would be on the diseases of metabolism.

Clinical Physiology.—The Department of Physiology of the College of Physicians and Surgeons, New York, offers to practitioners in medicine a course in Clinical Physiology, which deals with the application of physiological principles and methods to problems of practical medicine. The course, which consists of fifteen weekly exercises, will be given by Dr. R. Burton-Opitz, Dr. F. H. Pike, Dr. Haven Emerson, and Dr. H. B. Williams, on Thursday afternoons from 3 to 5 o'clock, at the college, 437 West 59th street, beginning October 3. The fee for the course is $15, with a matriculation fee of $5 in addition. Applications may be made to Prof. Frederic S. Lee at the College of Physicians and Surgeons.

Mississippi Valley Medical Association.—The thirty-eighth annual meeting of this association will be held at the Hotel Sherman, Chicago, Ill., on October 22, 23, and 24, 1912, under the presidency of Dr. Louis Frank of Louisville, Ky. The orations in medicine and surgery will be delivered by Dr. C. G. Stockton of Buffalo, and Dr. George W. Crile of Cleveland. Details may be obtained from the secretary of the association, Dr. Henry Enos Tuley, Third street Annex, Weissinger-Gaulbert, Louisville, Ky.

Washington State Homeopathic Medical Society.—At the annual convention held in Tacoma on August 30 and 31, the following officers were elected: *President,* Dr. George H. Dow, Chehalis; *Vice-Presidents,* Dr. C. P. Bryant, Seattle, and Dr. E. F. Larkin, Bellingham; *Secretary,* Dr. George Walter Beeler, Seattle; *Treasurer,* Dr. Thomas J. Appleton, Seattle. The next annual meeting will be held in Seattle.

International Congress of Gynecology and Obstetrics.—This Congress, which has just closed its sessions in Berlin, elected Dr. J. Riddle Goffe of this city president, and voted to hold the next meeting in New York City in September, 1915. Among other Americans who attended the Berlin Congress and read papers were Dr. Parker Davis of Philadelphia and Dr. Hermann Boldt and Dr. Arthur Stein of New York.

Publications of the Tropical Diseases Bureau.—In November the Tropical Diseases Bureau, which replaced the Sleeping Sickness Bureau on July 1, will commence the publication of the *Tropical Diseases Bulletin* under the general editorship of the director, Dr. A. G. Bagshawe. Each number will consist of about fifty pages containing

classified summaries of the current literature of the tropical diseases; they will appear, as a rule, twice a month. The annual subscription price will be one guinea, post free. The publishers will be the Messrs. Baillière, Tindall & Co. of London. The tropical diseases of animals will be treated in a separate publication, the *Tropical Veterinary Bulletin*. This will appear quarterly from October and will be in charge of Mr. A. Leslie Sheather of the Royal Veterinary College, London.

Honorary Degrees Conferred by Fordham University.—The extension course for practising physicians in the study of nervous and mental diseases was opened at the Fordham University Medical College on September 9, to last for three weeks, women being admitted to the lectures for the first time, it is said, in the history of a Jesuit institution. Over a hundred and fifty physicians attended the opening. On September 11 the university conferred the honorary degree of LL.D. on Drs. Henry Head of London, Carl Jung of the University of Zurich, Nicolas Achucarro of Madrid, and Horatio Robinson Stover of Newport, R. I. Dr. Gordon Holmes of London was made a doctor of science. The new Fordham Clinic, the building and equipment of which have cost over $200,000, was also opened recently.

The Association of Life Insurance Medical Directors.—The twenty-third annual meeting of this Association will be held in New York City on Wednesday and Thursday, October 9 and 10 in the Board Room of the Mutual Life Building, 34 Nassau street. The following papers will be read: President's address, "Some Studies in Family History," by Brandreth Symonds, M.D., Chief Medical Director The Mutual Life Insurance Company of New York; "Further Report on Blood Pressure," by John W. Fisher, M.D., Medical Director the Northwestern Mutual Life, Milwaukee, Wis.; "Selection of Female Risks in Whom Hysterectomy and Ovariotomy Have Been Performed," by P. H. Ingalls, M.D., Assistant Medical Director the Ætna Life Insurance Company, Hartford, Conn.; "The Significance of Some Urinary Constituents," by J. Bergen Ogden, M.D., Assistant Medical Director the Metropolitan Life Insurance Company, New York City; "A Study of Chest and Abdominal Measurements in Relation to Build," by Faneuil S. Weisse, M.D., Medical Director the Mutual Life Insurance Company of New York. The annual dinner of the association will be held on Wednesday, October 9, at 6.30 P.M., at the University Club, Fifth avenue and 54th street, New York City. Further information regarding the meeting can be obtained from the secretary, Dr. William Evelyn Porter, 34 Nassau street, New York.

Obituary Notes.—Dr. George H. Cocks of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1882, a member of the American Medical Association, the New York State and County Medical Societies, the Academy of Medicine, and the New York Ophthalmological Society, assistant surgeon to the New York Eye and Ear Infirmary, and ophthalmologist to the Institute of Mercy, died at his summer home in Pleasantville, N. Y., on September 8, aged 51 years.

Dr. Horace Lewars died in the German Hospital at Philadelphia on August 26 as a result of uremia and paralysis at the age of 44 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1890. He was a retired officer of the First Regiment National Guard of Pennsylvania and during the Spanish-American War he took an active part in caring for the men when typhoid fever broke out in the camp at Chickamauga. He was a member of the Philadelphia Obstetrical Society.

Dr. William Dan Lamb of Lawrence, Mass., a graduate of Jefferson Medical College in 1846, died at his home on August 25, aged 88 years. He was closely identified with the early history of his native town, and served as an army surgeon during the Civil War.

Dr. Edouard Napoleon Fugere of McGregorville, N. H., a graduate of Laval University, Montreal, died on August 30, aged 49 years. He was a member of the medical staff of Nôtre Dame de Lourdes Hospital.

Dr. William T. Klein of New York, a graduate of the College of Physicians and Surgeons, New York, in 1895, and a member of the National Society for the Prevention of Tuberculosis and the Greater New York Medical Association, died at Sea Cliff, L. I., on September 7, aged 37 years.

Dr. Frank Edward Lewis of Albany, N. Y., a graduate of the Cleveland University of Medicine and Surgery in 1886, a member and vice-president of the New York State Homeopathic Medical Society, and attending physician to the Homeopathic Hospital of Albany, died at his home on September 10, after a long illness, aged 57 years.

Dr. Henry Strong Denison of Denver, Col., a graduate of the Johns Hopkins Medical School, Baltimore, in 1908, a member of the American Medical Association and of the Colorado State and Denver County Medical Societies, died suddenly at his home on August 28, aged 28 years.

Correspondence.

ANOPHELINES IN THE PHILIPPINE ISLANDS.

To the Editor of the Medical Record:

Sir:—May I venture to call the attention of your readers to an error in your Philippine letter dated June 14 in regard to the anophelines in the Philippine Islands? The writer says: "In view of the fact that no anophelines, even after most diligent search, have been found anywhere in the Philippine Islands (with the possible exception of one single specimen which is alleged to have come from the Philippines, and which is now in Washington)," etc.

I do not know where the writer got his information, but there could hardly be a greater misstatement. The anophelines are widespread and numerous throughout the islands, and include *Anopheles formosus* (Ludlow); *Myzomyia funesta* (Giles); *M. indefinita* (Ludlow); *M. ludlowii* (Theobald); *M. rossii* (Giles); *M. thorntonii* (Ludlow); *Stethomyia pallida* (Ludlow); *Myzorrhynchus barbirostris* (Van der Wulp); *M. pseudobarbirostris* (Ludlow); *M. sinensis* (Wiedemann); *M. vanus* (Walker); *Nyssorhynchus flava* (Ludlow); *N. fuliginosus* (Giles); *N. philippinensis* (Ludlow); *N. stephensi* (Liston); *N. theobaldi* (Giles); *Calvertina lineatus* (Ludlow).

The nomenclature is according to Theobald. In the eleven years I have been connected with the mosquito work for the Medical Corps, U. S. Army, I have handled thousands of anophelines from the Philippines, but *M. rossii* is one of those rarely sent in. There can hardly be said to be a

dearth of anophelines in the Philippines as a whole, but there are a few localities where they are seldom taken.

C. S. Ludlow.
Army Medical Museum and Library, Washington, D. C.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COST OF HOSPITALS—TROPICAL MEDICINE—THE AUSTRALIAN INSTITUTE—GOVERNMENT'S EXPEDITION TO THE NORTH—VITAL STATISTICS; LONDON RATES, RURAL RATES (ESSEX)—WOMEN'S CORPS CAMPING OUT—INSURANCE, MORE RESIGNATIONS—EXHIBITION—OBITUARY.

London, August 30, 1912.

Renewed attention has of late been directed to the cost of our London hospitals. On Tuesday the authorities of King Edwards Fund contributed some statistics of the expenditure in 1911, amplifying its annual report issued in April. There are 107 institutions connected with the fund, of which 17 are general hospitals, with an average of 100 beds in daily occupation and 15 with a lower average. The others are special: 4 for consumption, 5 for women, 6 for children, 3 epilepsy and paralysis, 5 ophthalmic, 12 cottage, 8 lying-in, and 32 unclassified. There were increases in the cost per bed and among out-patients amounting in 1911 to £9,600, against which it is stated must be set off economies of about £47,000 per annum effected since the first issue of the reports in 1904. It is said three factors tend to increase the expenditure: (1) tendency toward costly special treatments resulting from developments of medical science; (2) rise in prices; (3) danger lest success in effecting economies lead to slackness in the constant effort needed to maintain them.

It is important that where increase has occurred the committees should ascertain whether it has been unavoidable or due to preventable causes, particularly when the increase exceeds the average of similar hospitals. In the large general hospitals the increases occur under surgery and dispensary as well as maintenance (salaries and wages). In children's hospitals the increase in average cost is much heavier and more generally distributed over the different items of expenditure.

The Australian Institute of Tropical Medicine is making great progress. The Commonwealth Government has granted additional endowments to provide for extension of the work. From there new laboratories and special wards in the Townsville hospital are being erected. The universities of Sydney, Melbourne, Adelaide, and Brisbane will grant diplomas on the subject, leaving the teaching to the Institute. The Government will appoint representatives to control the arrangements jointly with the universities. The Institute has appointed Dr. Henry Priestley and Dr. Nicoll on the staff.

The report of the Australian Commonwealth's expedition to the Northern Territory to investigate tropical diseases shows that the occupation of the district by whites is mainly a medical problem. A fourth of the mortality is due to malaria. There are deaths from dysentery almost every year, besides epidemics which sometimes break out. Beriberi, ankylostomiasis, yaws, trachoma, and leprosy are also known, but generally have been so far sporadic. An important statement is that residents who live a reasonable life, taking adequate exercise and the precautions adapted to a tropical country, enjoy good health. Up to the present there is no evidence of the influence of the climate on the third generation, though it perhaps may have to be taken into consideration in the future. Dr. Breinl describes life on the stations as ideal with regard to health—an active outdoor life in the comparatively cool and dry winter experienced on the tablelands. But alcoholism is an enemy as much as malaria. The prominent lesson of the expedition is the necessity of skilled medical help. No precautions seem to have been in force in the mining settlements to restrain the spread of malaria or indeed any other condition. But the extirpation of malaria is not the only problem. The Territory is said to be exposed to infection from China and the Dutch Indies, and the sanitary conditions such that if once introduced tropical diseases would most likely assume an epidemic form. It is accordingly recommended that those diseases should be studied on the better known islands with a view of quarantine legislation. The necessity of this is indicated by the fact that one or two species of mosquitos known to abound in the Malay States have already been detected in the Northern Territory, showing that invasion from the East has actually taken place.

The facts mentioned in my last respecting the low birth-rate have since been illustrated and enforced by the return on Wednesday of the births and deaths during April, May, and June. In that quarter the births in England and Wales corresponded to a rate of 23.9 per 1000, which was 3.7 below the mean in the ten preceding second quarters and the lowest recorded in any second quarter. The natural increase of population by excess of births over deaths was 102,302, against 111,987, 119,154, and 105,812 in the second quarters of 1909, 1910, and 1911, respectively.

The deaths were equal to an annual rate of 12.7, or 1.7 below the mean in the ten preceding corresponding periods, and the lowest death rate recorded in corresponding quarters. London's rate was 12.4. The infantile mortality was at a rate of 89 per 1000 births, being 14 below the average in ten corresponding previous periods and the lowest on record. The deaths from epidemic diseases in the quarter totaled 8884.

Taking this closing month of August by itself, although it has been the wettest and coldest on record, still more favorable figures are reported and that especially in regard to infantile mortality, the difference between this year and last being chiefly due to the diminution of diarrhea, which is usually so excessive in summer. Many hundreds of children unquestionably owe their survival to the almost complete absence of summer heat, which so many of their seniors are lamenting.

Dr. J. C. Thresh, Medical Health Officer for Essex, has just issued his report for 1911, in which he touches on some of the above-mentioned facts, but in regard to his own district, one of the healthiest counties in the kingdom. The rural birth rate is there also falling and he says should have the attention of the State. He holds it to be affected by the dearth of good cottages and thinks owners might build them to return fair interest. But he admits that management and repairs may swallow up the returns, and the work should be done by public authorities.

Dr. Thresh reports that in his county the deaths from consumption are decreasing, but from cancer they have been continually on the increase and are now actually more numerous than from phthisis.

The Women's Sick and Wounded Convoy Corps

was founded about three years ago to provide efficient training for service in voluntary aid detachments in conformity with the requirements of the Red Cross Society. The training is based upon the R.A.M.C. system. The corps has gone into camp under its commandant-in-chief, Mrs. St. Clair Stobart, and in spite of the most adverse weather the members have carried out their duties with energy and even enthusiasm. Commandant Stobart requires the strictest discipline, and the daily program this week is exacting from reveille at 6 A.M. to "lights out" at 10:15 P.M. Night watches are kept from 10 to 2 A.M. and 2 to 6 A.M. The work of the camping out is no pretense. Everything is done by the members of the corps, even the pitching and striking of the tents and the digging of the camp fire trenches.

Another resignation from the Advisory Committee appointed under the National Insurance Act has taken place, that of Dr. Herbert Jones, Medical Health Officer for Herefordshire, one of the fourteen medical members who refused to resign at the request of the British Medical Association, declaring that they considered their duty "for the present" was to remain on the committee.

The medical staff of the Swansea Hospital informed the Board on Wednesday that they will be unable to give their services to persons insured under the Act when the medical benefit comes into operation except in cases of urgent necessity. Dr. Knight, on behalf of the staff, explained that these cases were accidents or serious diseases. Their only contention was with the Government which sought to impose on them heavy duties on impossible terms. It was said to concede their demands the Chancellor would have to find more than three millions, but Dr. Knight asked what would it cost to pay for the services now given gratuitously? He calculated in that hospital the surgical operations performed in a year, at five guineas each, would cost ten thousand, and that had hitherto been done gratuitously. The Board decided to hold a special meeting to discuss the matter.

An exhibition of modern appliances for the treatment of tuberculosis has been opened this week and will remain open for some time. It was organized by the Society of Medical Officers of Health and seems likely to succeed. Demonstrations and lectures are to be given at intervals. Hygienic measures, in relation to cookery, disinfection, open air shelters, are largely represented.

Mr. Clinton T. Dent, vice-president of the Royal College of Surgeons, senior surgeon to St. George's Hospital and chief surgeon to the London police, died on the 26th inst, aged 61 years. He took the M.R.C.S. in 1875 and proceeded to the fellowship two years afterward. He lectured in the school of St. George's when elected on the hospital staff, first on physiology, then on surgery. He became a member of several societies, contributing papers to them and to the journals. He was elected to the council of the college and in due course on the Court of Examiners. He also served for some time as examiner in surgery to the University of Cambridge, which in 1899 conferred on him the honorary degree of M.C. He wrote the "Nature and Significance of Pain," which you will probably remember. He translated and edited Billroth's "Clinical Surgery." The "Medico-Chirurgical Transactions," Heath's "Dictionary of Practical Surgery," Tuke's "Dictionary of Psychological Medicine," and the volumes of "Mental Science" were also indebted to his pen for illuminating articles. Besides his professional work, Mr. Dent was an explorer and mountaineer of distinction. He became president of the Alpine Club (1886-9). He conducted a series of explorations in the Caucasus. He wrote the volume on "Mountaineering" in the Badminton Library and many articles on Alpine as well as surgical subjects. In 1899 and 1900 he was in South Africa as an independent surgeon and the result was a series of letters on "Gunshot Wounds" in the *British Medical Journal*.

Mr. Edgar Jones, J.P., who died on the 26th inst. in his 103d year, was probably the oldest member of the profession as well as the senior magistrate. He took the membership of the Royal College of Surgeons in 1834 and practised for some years at Saffron Walden in Essex, but later he devoted himself to agriculture. In 1852 he was put on the Commission of the Peace and eventually became chairman of the Billericay Bench. King Edward sent him a telegram of congratulation when he attained his 100th birthday. A few months ago he met a centenarian woman and they exchanged reminiscences. Mr. Jones was a life abstainer from alcohol and tobacco. He retained his faculties in a remarkable degree.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

MEETING OF THE CANADIAN MEDICAL ASSOCIATION AT EDMONTON, ALBERTA.

TORONTO, Sept. 10, 1912.

THE annual meeting of the Canadian Medical Association took place this year on August 10, 12, 13 and 14 at Edmonton, Alberta. This is only the third time that the association meeting has been held in the West. Twenty-three years ago it was held in Banff, and in 1904 in Vancouver. The meeting at Edmonton was successful from many points of view; the attendance, considering the distance to be traveled before reaching Edmonton from Eastern Canada was excellent, and the papers generally were good.

Dr. H. G. MacKid, of Calgary, the president, gave an inspiring address filled with enthusiasm for the West and with wonderful predictions for its future. Dr. MacKid said in part that the outstanding need of the medical profession in Canada today was a closer and more thorough organization of the medical men in their respective district, county, and provincial associations, which as a result would find their fullest and proportionate representation in the National Medical Association. Reference was made to the passage of the bill which made interprovincial medical reciprocity possible, and a glowing tribute was paid to Dr. Roddick, of Montreal, for his untiring efforts to bring this about.

Dr. MacKid spoke of the value of the *Canadian Medical Association Journal* and said that, thanks to the labors of the finance committee of the past two years, an efficient journal had been established, which, under the able editorship of Dr. Macphail, had already won for itself a place in the periodical literature of the medical world. It was hoped that within a short time it might be made a weekly instead of a monthly. That, however, would depend upon the support given the association by the profession at large throughout the country.

Attention was also drawn to the affiliation of the various provincial associations with the Canadian

Medical Association, which had been carried through during the past twelve months. At present all of the provinces save one had declared themselves in favor of affiliation and had become affiliated.

After commenting on things done the speaker considered the needs of the future. According to him the great problem now is to get the Canadian Medical Association solidly cemented together. The establishment of the journal had been a long stride in this direction. The next step was to create a properly constituted central body, a sort of parliament, with proportionate representation from each province. First, however, county societies must be organized, and in those districts where none existed they must be created.

Dr. MacKid gave unstinted praise to the efforts of the American Medical Association to improve the standard of medical education, to uproot commercialism, and to abolish quacks and proprietary medicine and fake cures. In closing the speaker sketched in glowing and enthusiastic language the future of medicine in the West. Dr. A. E. Giles, London, Eng., gave the address in surgery.

A decidedly novel feature of the meeting was the fact that on the Sunday preceding the general sessions several pulpits in Edmonton were occupied by medical delegates. Sir James Grant, of Ottawa, occupied the pulpit of Knox Church and delivered a striking health homily from the text, "Turn ye, turn ye; why will ye die?" Sir James discoursed eloquently on health matters and especially on tuberculosis, and wisely pointed out that in a new city as Edmonton was it was important that the utmost care should be taken in its drainage facilities, as defects in drainage and sewer utilities was a cause of many diseases. Dr. Bruce Smith, of Toronto, preached a sermon on health in the Metropolitan Methodist Church, taking as his text, "It doth not appear what we shall be. The earth is the Lord's and the fullness thereof."

Among papers of interest read in the section was one that attracted marked attention by Dr. E. Ryan, superintendent of the Rockwood Hospital at Kingston, Ont. This paper, entitled "Seven Years' Advance in the Ontario Hospital for Mental Diseases," was somewhat of an indictment of the manner in which mentally deranged persons are treated in some localities and indeed were treated in Ontario seven years ago. Dr. Nicholls, of Edmonton, in discussing the paper, said that he had been informed by the Attorney-General that the only asylum in Alberta was so crowded with people of a low criminal grade that it left no room for anyone unless dangerously insane. According to the speaker, so far as the management and care of the insane was concerned in Alberta, they are now where Ontario was twenty years ago and not where it was seven years ago. He pleaded that the public take more interest in the matter and compel the government of Alberta to make more adequate provision for the cure of the mentally sick in the province.

The meeting was chiefly distinguished perhaps by its health sermons and by its popular lectures. On the evening of August 14 Prof. J. George Adami, of Montreal, delivered an address, taking as his text "The Sins of the Fathers." It was, in fact, an excellent scientific disquisition on heredity. He attacked the modern popularly accepted doctrine that acquired conditions are not inherited, and as a corollary that the germ cells are unaffected no matter what vicissitudes are undergone by the body at large, or rather, perhaps, by the body of the parent-at-large. This is to say that the sins of the fathers do not tell upon the children. These teachers prophesy that no matter how the parent ill treats his body prior to conception the progeny is unaffected; a man may have tuberculosis or syphilis, and provided he does not give the disease to the mother and so bring about infection of the fetus in the womb, the child is likely to be as strong and healthy as that of a perfectly sound parent. Adami stated emphatically that he was sufficiently old-fangled to repudiate this new-fangled "Weismannism," and he still held the belief that the sins so-called of the parents against the body, or at least a very important series of such sins, do influence the progeny to his hurt, and, what is more, he believed that these new-fangled ideas had their origin in the narrowness, or it might be said in the Chauvinistic provincialism of the zoologists. Adami went on to show that inheritance of disease was not everything, from the point of view of eugenics, the terrible effects of congenital disease and more particularly of infections conveyed to the growing individual while in the womb or during parturition must be considered. When it is accepted that at least half of gynecological practice is due to gonorrhea and its results, that a large proportion of the cases of infantile blindness is of gonorrheal origin, that as demonstrated by the Wassermann test, practically all cases of locomotor ataxia, and nearly all cases of general paralysis of the insane are of syphilitic origin; when we know that most cases of multiple successive abortions are syphilitic, and recognize the puny, miserable parodies of humanity doomed in most instances to an early death, that too often are the result of syphilitic disease in the parent; when we realize the preventable ills that follow in the train of these venereal diseases, the speaker said he wholly agreed that the time had come when we should no longer refer to these matters by circumlocutions, when for the good of the coming generations we should openly wage war against gonorrhea and syphilis, and above all should for the safety and welfare of our children instruct them as to the dangers they must ward against, not merely on account of their own health and happiness, but for the sake of the generations yet unborn.

Prof. H. A. McCallum, of London, Ontario, was elected president and London, Ontario, was selected as the next place of meeting. The Executive Council was elected as follows: Drs. Whilland, Edmonton; Findlay, Montreal; Adami, Montreal; Halpenny, Winnipeg; Reeve, Toronto; McKechnie, Vancouver; Small, Ottawa; Kennedy, Macleod; Daniels, St. John, N. B.; Madre, Halifax; Archibald, Montreal; Primrose, Toronto; Conroy, Charlottetown, and Young, Saskatoon. Dr. H. G. MacKid, Calgary, as president of the association will be a member of the committee *ex officio*. With true Western hospitality the medical men who attended the meeting were entertained in various ways. Trips were arranged to points of interest in the vicinity of Edmonton—vicinity being a broad term in that land of immense distances. Visits were made to points in the Rockies, only a question of a hundred miles or so, and a good impression was created of the great Northwest. The meeting was eminently successful both from the scientific and social viewpoints.

1. The Use of Lactic Acid Soured Milk and Lactic Acid Bacilli in Pulmonary Tuberculosis. P. C. Bartlett and C. V. Murphy.
2. Two Cases of Diverticulum of the Bladder Treated by Operation. A. L. Chute.
3. Present Status of Salvarsan. A. Post.
4. Two Cases of Orchitis Due to Mumps Treated by Operation. G. G. Smith.

1. Use of Lactic Acid Bacilli in Pulmonary Tuberculosis.—P. C. Bartlett and C. V. Murphy state that every clinician who has concerned himself extensively with the care of tuberculous patients has been impressed with the prostrating effect of the obstinate diarrhea, alternating very often with intervals of constipation, which is a not infrequent complication of well established, or advanced pulmonary tuberculosis. That the large percentage of these cases are functional only has been indicated by a somewhat extensive study of the feces in the laboratories of the Rutland State Sanatorium, and their toxic origin is strongly suggested. It is in connection with this type of individual, as well as in cases of actual tuberculous enteritis that the employment of lactic acid soured milk has afforded the maximum benefit, both as a dietary measure in support of energy and in tissue repair, and as an agent favorably modifying the symptoms and controlling the diarrhea. Its range of usefulness extends over almost the entire field of gastrointestinal affections encountered in connection with sanatorium work.

2. Diverticula of the Bladder.—A. L. Chute reports two cases of diverticulum of the bladder successfully treated by operation. The type presented by the two cases differed essentially from the clearly congenital double bladders, on the one hand, and also from the little herniæ of the bladder that are directly due to pressure and usually arise near the vertex. Diverticula, such as those in the reported cases cannot strictly be called congenital, yet the author believes they always have their origin in the little pits that one sees from time to time just to the outside of the ureteric orifice, and which are undoubtedly faults or anomalies in the development of the bladder. Embryologically buds from the fetal ureter, which might easily lead to such little pockets, are supposed only to arise to the inner side of the ureter, while these are seen on the outer side. Many writers note the frequency with which diverticula appear just outside the ureter, but the author has seen no explanation offered for this. He believes the most probable explanation lies in the little congenital pits or pockets. These are not confined to males. Their presence is not in itself sufficient to bring about the formation of a diverticulum. There must be the determining agent as well, such as an increase in the intravesical pressure. This may be due to obstruction at the bladder outlet, or anywhere along the urethra, or a sharp cystitis, attended with violent bladder spasms, may be sufficient.

3. Present Status of Salvarsan.—A. Post concludes that salvarsan is the most rapid and powerful antisyphilitic known. It is not without its dangers which are sufficient to induce caution in its use, but not to cause its abandonment. It is not yet possible to promise absolutely a cure. One should not urge its use upon those who are impressed by its possible ill effects. It should be used in conjunction with mercury in all cases in which a diagnosis can be made before general symptoms appear. It should be used in all cases in which patients are not progressing well under ordinary treatment in any stage. It should be used in all cases in which patients are an especial danger to the community. It should not be used in maximum doses, but rather in repeated medium doses and in exceptional cases in repeated minimum doses.

4. Surgery of Orchitis Due to Parotitis.—G. G. Smith reports two cases of orchitis of this nature on which he operated with the primary object of preventing, if possible, the atrophy which so frequently follows this affection. The method employed was based upon the theory that atrophy results from the increased intratesticular pressure caused by the inflammation. Relief of this tension obtained by slitting the tunica albuginea restores the circulation and preserves the testicle.

1. Yellow Fever a Strictly Human Disease. A. Agramonte.
2. Pneumonia in Children. H. Lowenburg.
3. The Wassermann Test. D. M. Kaplan.
4. Vesical Neoplasms. J. F. McCarthy.
5. Ten Sex Talks to Girls. I. D. Steinhardt.
6. Endourethral Chancre. E. H. Marsh.
7. A Completed Treatment for Tonsillitis. F. Griffith.
8. Massive Tuberculosis of the Liver. D. Felberbaum.
9. The Cinematograph as an Aid to Medical Education and Research. R. Matas.

1. Yellow Fever a Strictly Human Disease.—A. Agramonte states that the hypothesis is unsupported which avers that yellow fever may attack the lower animals and that thereby the causative agent may continue to spread or be kept alive for considerable periods without attacking human beings living in the same territory. Numerous attempts have been made to inoculate the lower animals with this disease, but these attempts have been unsuccessful except in one instance, the inoculation of a chimpanzee by Thomas, in Brazil. The author has inoculated animals with venous blood, fecal matter, and "black vomit" from human cases, and has even applied infected mosquitos to the abdomen of rhesus monkeys, without in any instance transmitting the disease. In view of these facts and inasmuch as the mosquito's life is not shortened by carrying the virus and does not seem to be in the least affected by the latter, the author concludes that yellow fever is strictly a human disease.

3. Wassermann Reaction.—D. M. Kaplan concludes that there are diseases other than lues giving positive reactions. The old method of amboceptor standardization does not consider all the obstacles that it is designed to overcome. The aging of the antigen is capable of producing inhibition in doses smaller than ascertained in the original gauging, and should receive attention on the day of the test. The patient's serum ought not to be older than forty-eight hours. Old sheep cells develop anticomplementary powers.

4. Vesical Neoplasms.—J. F. McCarthy presents the following conclusions, which, in the light of recent advances, would appear to serve as a more or less adequate working basis in the treatment of tumors of the bladder, though in reality each case should be considered on its individual merits. The Oudin spark treatment (cystoscopic) applies to small or moderate size growths, single or multiple, particularly the latter, which are accessible and apparently of a benign character. In the absence of a reasonably prompt effect, such treatment should not be prolonged. Except in the unusual case in which pronounced hematuria obscures the view, the method will supplant the suprapubic operation of coning the mucosa. The application of the spark should not be made in a cloudy field, as in such event it is inexact and dangerous. Growths of an infiltrating character and suspiciously malignant should very promptly be removed by resection through the entire bladder wall at least two centimeters beyond the mass, and when in close proximity to the ureteral orifice should include ureter transplantation. In the case of a very great number of outgrowths in the bladder which, while benign, are, from their very multiplicity, not amenable to the spark treatment, one should not forget that this same treatment may with much effectiveness be directed via the suprapubic opening. It is the author's hope that the employment of the d'Arsonval spark may offer something even of a palliative nature in such cases as appear to be beyond reach.

8. Massive Tuberculosis of the Liver.—D. Felberbaum notes that this condition is usually secondary to intestinal tuberculosis, and reaches the liver by way of the portals. The first step is a tuberculous pylephlebitis and thrombosis of the endohepatic branches, and later on tuberculous granulation tissue is deposited. A number of these granulomata coalesce and form conglomerate tubercles. These deposits are usually multiple and may soften down, giving rise to a tuberculous abscess, which may eventually discharge into a bile duct, similarly to a caseous focus in the lung, rupturing into a bronchus. The nodules appear as white masses of various sizes and shapes, surrounded by a thin fibrous capsule. The adjacent liver substance is compressed and may become pigmented. They resemble very much gummata, but may also simulate neoplastic growths, as in the case to be described. The symptomatology is very definite, no case having ever been diagnosticated during life. The liver may be enlarged; tumor masses have been felt during life. Jaundice does not occur. The cases have all been characterized by gradual emaciation, but on the whole, the symptom complex is masked by the primary affection. There are two cases on record in which the process in the liver was apparently primary, no other tuberculous foci being discovered. The disease is slightly more frequent in children, probably on account of the frequency of intestinal tuberculosis. The case reported by the author exemplifies the difficulties of the diagnosis *intra vitam*, especially in that it was considered to be a case of carcinoma of the stomach and liver, tuberculosis not having been suggested as a possible diagnosis by any one of the many who examined the patient during life. Even after the specimens were obtained, the condition was considered by nearly all who saw it as a malignant growth.

2. Physiological Basis of Thoracic Surgery.—By J. M. Flint. (See MEDICAL RECORD, Vol. 81, page 1245.)

3. Transverse Myelitis Type of Poliomyelitis.—A. L. Skoog describes the pathological findings at autopsy of a patient dying from acute poliomyelitis of the *foudroyant* type. He notes that the perivascular tissue, which must not be confused with the adventitia, comes first in the frequency and severity of pathological changes. The adventitia is a worthy second and its cells and fibers may be completely disintegrated by the thick invasion of cells. All coats of the veins are frequently involved. The large arteries have only their perivascular structures invaded; the moderate sized ones have the adventitia also invaded, and the small arteries or arterioles may have an infiltration of intima, elastica and muscularis as well as the frequently involved adventitia. It is possible that some of these severely involved vessels have necrosing tunics with resulting thromboses or ruptures of the walls. The author believes that the infiltrating cells give evidence of a defensive process, and all indicate the particular quantitative localization of the virus of acute poliomyelitis in the tissues.

4. Spinal Cord in Pernicious Anemia.—R. N. Willson reports a case of pernicious anemia with marked nerve center involvement and an interesting family history, and describes the complications on the part of the nervous system in this disease. It is well to remember that there are spinal cord and perhaps brain changes in every case of true pernicious anemia and the nervous symptoms may sometimes prevent its prompt recognition. The spinal cord lesions consist of a combined sclerosis of the posterior and lateral columns, the former sometimes being alone affected and producing the clinical picture of tabes. The lateral columns are never involved by themselves. A considerable number of cases have been reported in which the anterior horns were involved, but this is a late development in the disorder. In the case reported there was a very striking clinical indication of a pathological intestinal process dating back to childhood, and it seems evident that this toxemia led up to, if it is not absolutely demonstrated to be the direct cause of, the later symptoms. The family history suggests a possible hereditary luetic influence, since one sister of the mother died in an advanced stage of locomotor ataxia, while two other aunts and the mother herself suffered also from conditions which might have thus originated.

5. Difficult and Dangerous Labors.—H. A. Miller states that the normal progress of labor should be interfered with only when the mother or the child seems to be in danger. Judgment of each individual case should be carefully formed, applying all the known methods for measuring the pelvis, and the size of the child's head, and placing special importance on the possibility of engagement or non-engagement as the result of pressing on the uterus, and using the finger in the vagina, and the paw-like grip over the child's head. Due consideration should be given to the fact that a competent obstetrician has previously had difficulty and has secured a dead child from high application of forceps. As labor progresses, the borderline cases must be so conducted and at such a place as to permit of a cesarean section in preference to an application of high forceps, in case progress is not satisfactory and there seems to be a reason for hastening delivery. These cases should be conducted largely by abdominal palpation, judging of the descent by this method in preference to frequent and, many times, unnecessary vaginal examinations. In the absolute indications for cesarean sections they should preferably be done as soon as the patient fairly enters labor, accepting as evidence of the opening of the os some slight vaginal discharge, or, if necessary, one examination. In the relative indications for cesarean section it should be done prior to the time that the patient shows an unusual degree of exhaustion and preferably prior to the rupture of the membranes. In elderly primiparæ the possibility of a senile uterus must frequently be the determining factor in deciding as to spontaneous delivery, high forceps and cesarean section. High forceps should be applied only in cases in which the surroundings of the patient do not justify an abdominal cesarean and in which the head is floating free from the pelvis. The physician must be prepared to accept an infantile mortality in excess of 15 per cent. with a maternal mortality equal to elective cesarean section, plus a not inconsiderable morbidity. Pubiotomies should be done only when sufficient assistance is at hand to prevent undue separation of the pelvic bones and in cases in which a very slight increase of the conjugata vera is known to be sufficient to permit the passage of a living fetus. Craniotomy has no place in obstetrics on a living child, and the physician should avoid putting himself in the position of having to sacrifice one life to save the other when both should have been saved.

6. Cesarean Section.—C. A. Stillwagen notes that cesarean section may be said to be indicated generally in all cases of maternal or fetal dystocia, in which other methods of delivery are extra-hazardous to either mother or child. Therapeutic abortion is often too lightly undertaken. It is sanctioned by law and medical opinion, but this fact tends to diminish the sense of responsibility and to cause some unjustifiable operations. Craniotomy is rather condemned in a living fetus; it is doubtful whether this procedure is less dangerous than some forms of cesarean section. From a surgical viewpoint, cesarean section would be the quickest, surest and cleanest method of procedure in placenta prævia and is indicated in all cases of central placenta prævia and in the partial type when the child is living and near term, provided adequate surgical skill is available and the patient's condition makes her a fair operative risk. It is also a valuable recourse in eclampsia, emptying the uterus quickly, lowering the blood pressure, improving the chances for the child, etc. It is indicated in primiparæ with rigid cervix or any condition involving delay or unusual trauma to mother or child. The field of cesarean section is widening.

8. Poliomyelitis in Norway.—F. Harbitz points out that poliomyelitis has been recognized in Norway as a distinct disease since 1820, sporadic cases having been reported. Epidemics have occurred in 1858, 1886, 1889, 1903, 1904, 1905, 1906, the earlier ones being local, the later ones extending over wider tracts of country. The Norwegian physicians regard it generally as an acute infectious disease and also contagious, which view is shared by the author, who gives facts supporting his belief. Of great interest are the abortive cases which are found to be just as contagious as the severer ones, and it must be supposed also that the infection can be spread by means of healthy bacteria carriers, which explains the long period of incubation sometimes noted. According to Norwegian experience, the route of entrance is the nose, throat, and alimentary tracts. The degree of infectiousness as a rule is not very great. No evidence has been found that food is a source of infection, nor that there is a coexistent infection of animals. The unexplained points are the prevalence of epidemics in certain years without reference to changed climatic conditions, the greater prevalence in the summer and fall, and in rural districts, and lastly, the varying degree of contagiousness in different epidemics. Notification, isolation, careful disposition of the patient's excretions and secretions, especially from the nose and throat, general disinfection of articles in contact with the patient, particular attention to the lighter abortive cases and possible carriers, and care as to the hygiene of school children, and even the closing of schools, are the precautionary measures that have been taken. As a rule these have been begun too late, but they seem to have helped to limit and stop the disease. The treatment of individual cases has been mainly symptomatic, and possibly of not much avail. Systematic investigation of the disease is now being carried on.

12. Palliative Treatment of Terminal Laryngeal Tuberculosis.—H. Horn recommends as a palliative measure in cases of terminal laryngeal tuberculosis the Hoffman method of injecting the superior laryngeal nerve so as to produce a permanent anesthesia. The emaciation which is usually present makes the procedure generally an easy one. The point of entrance of the nerve through the thyrohyoid membrane can be palpated with exactness. The exact technique of making the injection is as follows: The skin is first prepared by painting the region to be injected with iodine. The left side of the larynx is grasped with the first and second fingers of the right hand, and with the thumb of the same hand the painful point is located. As soon as this spot is found the thumbnail is pressed in to mark the spot and the needle is introduced at this point. The needle is introduced perpendicularly for 1.5 c.m.; then the point is moved in all directions until a sharp pain, radiating to the ear, is felt. From 3 to 5 c.c. of a warm solution of 85 per cent. alcohol are then injected until the pain in the ear disappears. The point of entrance of the nerve will be found just at the upper edge of the thyroid cartilage, about one-third of the distance from its outer edge. In no case has the author had any untoward effects and claims that the procedure is entirely without danger. There is immediate relief from pain as the aspiration of food is seldom observed. The injection can be repeated without danger as often as necessary and the relief lasts from a few hours to forty days. The mental effect on the patient is a very important secondary one. He becomes more cheerful and tries to take food. In three cases the results were negative, and if there was an involvement of the epiglottis, especially on the external surface, it was found that the relief failed or was only partial.

4. A Note on the Morphology of a Strain of Trypanosoma Equiperdum. W. Yorke and B. Blacklock.

1. Intraneural Injections of Alcohol.—O. May concludes that alcohol, injected into the trunk of a peripheral nerve, produces a more or less complete local necrosis of the nerve at the point of injection. The change is not an "ascending" one, the nerve above the point of injection remaining normal; the cells of origin of the fibers may show some degree of chromatolysis, but do not exhibit signs of permanent injury. The conditions produced by such injection are more favorable to regeneration than those resulting from simple section without suture. The anatomical continuity of the nerve trunk favors rapid regeneration, though this is to some extent retarded by the fibrosis which occurs to a greater or less extent in every case of alcohol injection. It is apparently impossible by a single injection of alcohol to produce complete necrosis of the Gasserian ganglion, its dense texture preventing complete infiltration. The alcohol tends to find its way under the sheath of the ganglion towards the proximal root, which is affected to a greater degree than the actual ganglionic.

2. Gray Hair Associated with Nerve Lesions.—G. L. Cheatle notes the following observations that he made on the case of a male patient, aged 36 years, who had subcutaneous neurofibromata growing on the cheek and forehead of the right side, which were noticed about the same time ten years ago, when the hair also began to grow gray. The state of the grayness of hair was as follows: On the mid-orbital maximum point of Henry Head, there was a patch of normal brown color, which appeared as an island in a completely gray V-shaped area behind which, and limited behind by the posterior boundary of the fifth nerve, was an area of scattered gray hairs. There was no disturbance of sensation. Tactile, heat, cold, and pain sensations were normal. The author believes it would be of theoretical and practical interest to discuss the state of grayness of hair, together with the protopathic nerve influence described by Head. The discussion would be very discursive, owing to the fact that one's knowledge is not sufficient to enable one to state what makes hair appear gray. The author believes that the above case illustrates an epithelial change in state, which takes place *pari passu* with a change in the nervous system, and, therefore, probably due to it. Although grayness of hair is of itself an unimportant epithelial change, it appears at a time of life common to another and important epithelial change—namely, cancer. The genesis and etiology of an unimportant change in a tissue may illuminate

AUTOINTOXICATION IN THE ARMY.

THE *Journal of the Military Service Institution of the United States* awards annually the so-called Seaman prize for the best essay on a subject selected by the founder of the prize, Major L. L. Seaman, and approved by council. The subject for last year was as follows: "How can autointoxication, that rarely recognized disease which has directly or indirectly caused more invalidism and mortality in modern armies than all other pathogenic causes combined, be prevented?" And the prize was awarded to Captain Nathan S. Jarvis, U. S. Army, whose essay on the subject is published in the July-August number of the journal. The subject selected is one that may cause surprise in the mind of the general reader. That such picked men among young adults of the nation as soldiers must necessarily be are sufferers from autointoxication, especially when it is remembered that their diet is for the most part very simple, may indeed be doubted. And Dr. Jarvis properly states at the very outset of his paper that the premise implied in the subject "may be true as a rash guess, but it cannot be proved by the usual methods of deducing medical statistics." He then gives a historical survey of the theory of autointoxication, and summarizes as well the views of such men as Combe, Vaughan and Novy, Fischer, *et al.*

So far as the army is concerned, Jarvis thinks that careful attention to the treatment of slight as well as severe intestinal disease should be insisted upon, because such conditions invite the absorption of poisons from the digestive tract. So far as the diet is concerned, he thinks that that of the American soldier compares favorably with the diet of other armies. However, boiling or cooking all food is advised so as to insure against chance infection and especially the use of such beverage as weak tea instead of water. Jarvis warns against the dangers of canned provisions, which are safe enough if properly prepared before canning and cooked immediately after being removed from the can, but are a source of various morbid conditions if carelessly packed or kept some time in unsealed receptacles. Of the direct methods of fighting autointoxication Jarvis mentions the usual intestinal antiseptics and the mechanical measures calculated to clear the intestines of putrefactive material or diminish the activity of certain microorganisms.

In acknowledging the careful work of the author in summarizing what is known about autointoxication, we think that the subject, selected presumably as of interest to the great body of army medical men, was a very unfortunate one. This subject has given rise to a prolixity of quasi-scientific literature in the general medical press, has been exploited by promoters of various drugs, modified foods, drugless methods of treatment, etc., until the laity and not a few medical men have been misled into thinking that autointoxication is a clear and easily diagnosed condition, instead of an obscure entity, the very existence of which has been doubted, and proofs of which so far brought forth are certainly not entirely satisfactory. Much loose thinking and purposeless treatment has resulted to the detriment of the profession and patients as well.

The subject needs the light of careful clinical observation and unbiased laboratory work, but such work in the study of autointoxication cannot be done in the army, where the material is least favorable for the development of the condition. We call attention with great pleasure to the much more promising subject for the next award of the prize, the full wording being as follows: How can the Medical Departments of the Army, Navy, and Public Health Service be best utilized for research work in connection with a department of public health? This subject is of more than mere local importance for the army and navy, and the paper awarded the prize will be awaited with interest by the general medical public.

THE TREATMENT OF TETANUS WITH CARBOLIC ACID.

THE enthusiasm which followed the remarkable results obtained by the use of diphtheria antitoxin led the medical profession to believe that in serotherapy was to be found all the promise of future success in the treatment of infectious disease; drugs and other non-biological methods of treatment were for a time scorned by the laboratory enthusiasts. However, it was soon shown that what was possible in diphtheria could not be duplicated in other infections, the mortality of which was not at all affected by various antitoxins however prepared. Vaccines were then brought forward, still in the enthusiastic preference of biological methods of treatment, and for a time these were hailed as the real deliverers of suffering mankind. At the present time, however, the general consensus of opinion is that vaccines hold a subordinate, though quite an actual, place in the therapy of infections. They may be fraught with great possibilities, but our methods of using them have so far given but very modest results.

The enthusiasm over serotherapy was best shown by the great hopes which greeted the production of tetanus antitoxin. For a time it seemed as if this dread disease was to be made quite innocuous, provided antitoxin was used. But soon enough it was shown that, however great its prophylactic value, the tetanus antitoxin possessed no curative value whatever. Now and then a patient treated with it recovered, but usually the case was one of mild

nature with a long period of incubation. The best test of antitoxin was made by the Russians during the late war with Japan, and both the published and private opinions of Russian military surgeons have completely denied it any therapeutic virtue.

Meanwhile, the Italians have been using a very simple method of treatment suggested years ago by Baccelli, and have finally succeeded in attracting the attention elsewhere by the remarkable results obtained. Baccelli's treatment consists in subcutaneous injections of carbolic acid in 3 per cent. dilution, given frequently enough to make the total quantity of pure phenol injected daily equal to from 0.3 to 0.5 c.c. (5 to 7.5 grains). Imperiali, writing in 1910, gives the results obtained in a sufficient number of cases to exclude merely chance results. Of fifteen patients with the foudroyant form of tetanus, only one patient recovered (mortality, 93.3 per cent.); of thirty-nine patients with a very severe form of the disease, twenty-two recovered and seventeen died (mortality, 43.5 per cent.); of ninety-four cases with the usual severe form of the disease, ninety-two recovered and only two died (mortality, 2.12 per cent.). Richter gives the average mortality, with the usual methods of treatment, as 88 per cent.; during the Civil War the mortality among the Federal troops was 92.56 per cent.; and Behring himself grants that the mortality of those treated with antitoxin reached 88 per cent. In a later paper Baccelli gathers one hundred and ninety cases treated by his method, and states that the mortality in these was 17.36 per cent., a figure that about equals the percentage of recoveries among the cases treated with antitoxin and other methods.

The above résumé is gleaned from a paper in the *Russkii Vratch* (Vol. XI, No. 28) by N. A. Goulyaeff, who had gone through the enthusiasm over the use of antitoxin and the subsequent disappointment. Lately, he had a chance to treat two very severe cases of tetanus by the Baccelli method, and to his great surprise both recovered. The first one had an incubation of eight or ten days, and when brought to the hospital was suffering from severe muscular spasms, frequently involving the respiratory muscles. Goulyaeff used 14.5 c.c. of pure phenol in the course of about five weeks in treating this patient, and is convinced that the drug has some actual quantitative relation to the amount of toxin present, for the diminution in the daily quantity injected was several times followed by an increase in the tetanic spasms. The second case was one of "cephalic tetanus" appearing after an incubation of six days. This variety of tetanus has frequently given 100 per cent. mortality. Goulyaeff's patient received 5.4 c.c. of phenol in two weeks and recovered completely. In neither case were any untoward effects noted from the administration of carbolic acid; the urine was carefully followed to note any such effects.

In America the saner methods of celebrating Independence Day have resulted in a marked diminution of cases of tetanus. However, such cases occur not infrequently in every large hospital and in the practice of most surgeons, and Baccelli's method of treatment should certainly be again tried. Not the least thing in its favor is its utter simplicity, which permits its use amid the most inadequate surroundings of any practice.

STATE MEDICAL SERVICE IN GREAT BRITAIN.

In various discussions of the new British insurance scheme it has been pointed out that it is not the principle of the bill to which the medical men of England object, but the obviously unfair manner in which Mr. Lloyd George has proposed to deal with the profession. The pay offered physicians of Great Britain under the insurance scheme was inadequate, and moreover they would be placed in the hands of the approved societies. Nearly all, however, laymen and medical men, are agreed that the objects of the bill are sound and that eventually England must adopt a scheme of this nature. Therefore when it was decided at the recent meeting of the British Medical Association to oppose the bill in its present form, the conclusion was also reached that to be consistent medical men themselves must bring forward an alternative scheme. Otherwise, the supporters of the measure would say, "you have wrecked a plan the principle of which you approve, and have not suggested anything in its place; consequently you must have taken this course impelled by merely selfish motives."

Fortunately, an alternative scheme was proposed at the meeting just over, and from a perusal of the same it appears to be, in its main features, both feasible and reasonable. Dr. Rentoul of Liverpool read a paper at the meeting referred to in which he stated his views as to the initiation of a State medical service. He is one of those who hold that the medical profession is now pledged to the formation of some such service and points out that nationalization of medicine in Great Britain is not so far off as some think. The thin edge of the wedge has been inserted already, for the State now appoints many official physicians, the number of which is increasing daily. Rentoul suggests as the chief points bearing upon a public health service the following: (1) That the insurance committees receive from the Insurance Commissioners a sum of money equal to about $1.50 per insured person per annum, this to be handed quarterly to the doctor of the insured person. (2) That the Insurance Commissioners give 60 cents per annum per member to the doctor or druggist, who agrees to supply the insured person with medicine. Thus 60 cents plus $1.50 would be the minimum sum asked for by the British Medical Association. (3) In order to meet Mr. Lloyd George's objection that he cannot or will not grant the amount asked for per member per annum, Rentoul would suggest that each insured person pay a yearly sum of $1.25, or about two cents weekly, to the doctor. In other words, that they pay the amount the better class friendly societies now pay their doctors. These three sums of $1.50, 60 cents, and $1.25 would, with 14,000,000 insured persons, give the doctors an annual income of about $2,360 each, exclusive of confinements, vaccinations, notifications, operations, sanatoria,

etc., these probably totaling from $250 to $500 each doctor yearly.

Rentoul contends that medical men at the present time give more in charity, principally in gratuitous services, than do the members of any other profession or trade, and that it is time that the public cease to impose upon them. He characterizes as brazen effrontery the suggestion of the Chancellor of the Exchequer that the present income of medical men in Great Britain should be further reduced yearly by $14,000,000. He is also of the opinion that an eight hundred dollar income limit should be adopted, with a sliding scale of income at, say, $300, $400, $500, and $800, the yearly contribution by the insured person to vary with the income.

Attention may be drawn to the fact that German practitioners under their insurance scheme get more by far than is proposed by the British Medical Association. At Leipzig, medical men have been granted $3.75 per annum, while the average German allowance for drugs is about 94 cents. Some form of insurance is sure to come in every European country, and the formation of a National State Medical Service as suggested by Rentoul appears to fit in with the tendency of the times. Conditions in this country so far as the medical profession is concerned are not too rosy. In all the big cities societies and lodges are increasing, and the physician's income is at the same time decreasing. It may not be long ere a scheme for State insurance or nationalization is mooted here, and therefore it is well that physicians of this country should watch the course of events in Europe and endeavor to profit by experience gained there.

INTESTINAL INFANTILISM.

The late Dr. Herter of New York published a small monograph on what he termed "Intestinal Infantilism," which affection he attributed in some manner to the persistence of the intestinal bacterial flora of the nursling period. At a later period Prof. Heubner, who recognized the clinical entity, assigned as its cause a congenital intestinal insufficiency, the presence of the flora thus becoming, we suppose, the effect and not the cause of the condition.

At a recent session of the Charité Hospital Physicians of Berlin (*Berliner klinische Wochenschrift*, August 19) Eckert presented two patients with this form of infantilism. There was a uniform arrest of development dating from an early period of childhood. One child aged 11 years appeared to be seven years younger. The individual finds were numerous and complex. Failure to improve under pancreas therapy seemed to show that the condition was not akin to Bramwell's pancreatic infantilism. Thyroidin was then exhibited with brilliant results as far as amelioration of the symptoms was concerned. Whether the children will start to regain their growth cannot yet be foreshadowed, as the observation period is too brief.

The most striking improvement was seen in the locomotive system. The youngest child, but four years old, had been extremely backward in walking and speech, although there was no actual mental defect. Under thyroidin she began to improve rapidly and was soon running about and talking. As Herter showed, this form of infantilism is attended by severe chronic diarrhea, and this condition responded in part to the treatment.

Viereck's new diagnostic method, based on testing the chromaffin system, was practised. Glucose and adrenalin given simultaneously produced glycosuria, showing abnormal tonus of the sympathetic nerves. Atropin caused tachycardia, pilocarpin was inert. The stigmata of the exudative diathesis and lymphatism were wholly wanting.

The pancreas was plainly in abeyance as hardly any trypsin was poured into the intestine. The author believes that that organ was stimulated indirectly through the thyroid. The thyroid of the patients could not be felt. The infantilism was certainly not myxedematous, although there were a few symptoms in common with myxedema, such as the scanty dry hair.

PARADOXICAL DIPHTHERIA.

The abnormal course sometimes pursued by individual and family diphtheria was no doubt largely responsible for some of the antagonism shown toward serotherapy, both when the latter was first introduced and also subsequently. We can comprehend this antagonism to-day when the position of serotherapy has become fixed in certain episodes which are reported from time to time. Thus Jess, before the Medical Society of Kiel last June (*Münchener medizinische Wochenschrift*, August 20), stated that he attended a child with lacunar tonsillitis as the clinical diagnosis, the bacteriological examination being negative. Two days later a second child was attacked with clinical diphtheria as the diagnosis aand both children were given serum without waiting for the bacteriological diagnosis, which was later positive for the second child. Both children promptly and uneventfully recovered as far as diphtheria was concerned, but both developed serum disease after recovery, which also ended uneventfully. About one year later, corresponding to the annual recurrence of anginous affections, one of the children again developed what was clinically a lacunar angina without any marked systemic reaction. The condition was persistent and examination showed diphtheria bacilli in pure culture. Fear of anaphylaxis prevented serum injection. The tonsillar patches persisted under vigorous local treatment for several weeks, finally becoming sterile as to diphtheria germs. The sister received no prophylactic injection for fear of anaphylaxis, but contracted nothing. The patient during the more than five weeks of diphtheria had shown only a slight evening rise of temperature as evidence of toxemia. The author also knew of a similar episode and the sole way of explaining these second attacks is that ordinarily both the first attack and the serum injections would have secured a considerable period of immunity, but in these cases neither afforded any protection worth mentioning.

BOTRYOMYCOSIS.

The peculiar raspberry-like formations which sometimes follow wounds of the hands and other exposed localities have probably been regarded by the laity and family practitioner as nothing more

than a special form of "proud flesh." They have also been seen in the horse, and at one period were believed to have been caused by inoculation with an unknown parasite. Inferentially the same causation was attributed to the human form. The attempt to introduce the term botryomycosis into familiar use seems, however, to have been attended with failure. The Germans prefer the term pyogenic or telangiectatic granuloma, and despite the peculiar clinical form the consensus of opinion has attributed the lesion to some unexplained activity of ordinary pyogenic cocci. The most peculiar feature of this lesion, however, is its tendency to recur when removed. At a recent meeting of the Kiel Medical Society (*Berliner klinische Wochenschrift*, August 12) Konjetzny was able to demonstrate two cases of this affection. He was unable to point to any new causal agent to explain its nature, but his histological studies led him to believe that these formations are tumors and not mere granulomata. The abundant new formation of blood vessels and the coincident occurrence of sarcoma-like tissue would apparently show the presence of a proliferating angioma or angiosarcoma. It may have been more than a coincidence that one of these growths developed on the site of a minute vascular birthmark. These tumors of traumatic origin may also have affinities with keloid formations.

News of the Week.

Yellow Fever in Mexico.—A recent report states that yellow fever has been present in Mexico since August 1, 1911. During that time sixty-eight cases with thirty-two deaths were reported in Merida. In San Juan Bautista, in the State of Tabasco, there were between May 4 and August 10 of this year a total of fifty-three cases of the disease with twenty-two deaths. The disease is now reported to be epidemic in Frontera, a port fifty-five miles from San Juan Bautista, having been carried from the latter place by troops transferred to Frontera, and Acting Assistant Surgeon J. F. Eaves has been assigned to temporary duty in the American Consulate at Frontera for the purpose of fumigating vessels and performing other necessary quarantine work on vessels prior to their departure for ports in this country. The disease has also been epidemic during the summer in Chile, and cases have occurred in Brazil, Colombia, Ecuador, and Venezuela. Investigation has shown that in certain localities of South America and on the west coast of Africa, and in Central America and southern Mexico yellow fever is endemic and has become a disease of childhood, the adult natives possessing immunity acquired by infection in early life. These endemic foci are a constant menace to all ports having commercial relations with them.

Smallpox in Pennsylvania.—During the week ending September 13 sixteen deaths from smallpox occurred in Pittsburgh, and on that day thirteen new cases were reported, making a total of 178 cases then in the city. Hundreds of persons are leaving the town, and in some quarters where the streets are roped off and quarantine lines are maintained by mounted police the inhabitants are in a state of panic. City physicians are vaccinating all of the school children, the members of the police force have also been vaccinated, and the street car company has ordered the vaccination of its motormen and conductors. The Health Director of the city is one of those who has contracted the disease. An epidemic of smallpox has also broken out in Carbondale, Pa., more than fifty cases having been reported. The Pennsylvania State Department of Health has taken charge of the situation.

Typhoid Fever at Allentown.—Upward of twenty-five cases of typhoid fever, with at least two deaths, have appeared within a short time in a newly annexed portion of Allentown, Pa. At first it was thought the water supply was at fault, but investigation disclosed the fact that almost all of those attacked received milk from one original source of supply.

Polluted Oysters.—The menace of oysters infected with typhoid germs is the subject of a report recently issued by the United States Department of Agriculture as the result of an investigation into an epidemic of typhoid fever occurring in Goshen, N. Y., in October, 1911. The source of infection in this instance was traced to oysters from Jamaica Bay, the investigator declaring that millions of gallons of sewage were discharged daily into the bay, around and even directly over the oyster beds. The Sanitary Superintendent of New York, however, states that there is no danger of another outbreak, and that, as a matter of fact, the oysters became contaminated, not in the bay itself, but in the freshening grounds further back in the meadows. Following an inspection of the oyster beds made by the New York Department of Health last spring, the small sewers polluting the freshening grounds were destroyed as much as possible. Examination of the water in the bay, it is alleged, shows that there is no danger of contamination because of the immense volume of water and the strong tides. This statement one may be permitted to doubt.

Liner Brings Smallpox.—The Italian SS. *America*, which arrived in New York on September 11 from Naples, was detained at Quarantine because of the presence of a case of virulent smallpox on board. The patient was removed to Hoffman Island together with 574 of the steerage passengers and crew with whom he had come in contact, and the other passengers after vaccination were allowed to land.

Deaths in New York.—During the week ending September 7 there were 1,229 deaths in New York City, the death rate per thousand being 12.39, as compared with 13.24 for the same week of last year, when the total number of deaths was 1,265. Of infants under one year of age there were 319 deaths, 50 less than during the preceding week.

Medical Examinations.—The State Board of Medical Examiners of California announces that of the 200 physicians who took the recent examinations, over 80 per cent. had passed successfully and had been granted licenses to practise.

Deaths of Aviators.—On September 11 Lieut. Siebert, an aerial scout in the German Army maneuvers, was killed by the fall of his aeroplane and his companion was seriously injured. This was the sixth fatal accident in six days among army aviators alone.

Infantile Paralysis.—Reports from Buffalo state that up to September 9 there had occurred in that city within the last few months 220 cases of infantile paralysis, with twenty-six deaths and permanent crippling in 60 per cent. of the survivors. Four new cases were reported on September 8. The disease has also been epidemic in Southern California, and from June 8 to August 17, a total

of 226 cases were reported in Los Angeles, with forty-three deaths.

"Open Window" Class.—In Montclair, N. J., where one of the first open-air schools for delicate children was opened, an "open window" class has been started in the Hillside Grammar School, to be followed by other classes of the same sort as seems desirable.

Radium Supply.—On behalf of the Bank of Radium of Paris and of Madame Curie, arrangements have been made for the purchase of property in Meeker, Col., containing the largest carnotite deposits in this country. The property is being acquired in the hope that radium will be found in sufficient quantities to permit of greater researches by the French scientists. In addition to radium carnotite, which was named in honor of President Carnot of France, contains radium salts, uranium, and vanadium.

Health Department Needs.—The New York City Department of Health has submitted to the Board of Estimate a request for an appropriation for the year 1913 of $4,510,308.25, which is an increase of $1,367,921 or 43.5 per cent. over the amount allowed for the current year. A considerable part of the increase is desired for raising some existing salaries and providing salaries for positions to be created.

For Health Conservation.—At a meeting of prominent Democrats held in the Colony Club, New York, on September 9, a bureau of health conservation in the interest of pure food and the consequent maintenance and improvement of health was formed, with the following officers: *President,* Dr. Harvey W. Wiley of Washington; *Vice-President,* Prof. Irving Fisher of New Haven; *Secretary,* Mrs. J. Borden Harriman of New York; *Permanent Committee,* Dr. J. N. McCormack, Bowling Green, Ky., representing the American Medical Association; Major W. O. Owen of Washington; Dr. Richard C. Newton of Montclair, N. J., and Dr. E. R. L. Gould and Dr. Thomas Darlington of New York. The formation of the bureau is a consequence of the health plank in the Democratic platform.

Gifts to Charities.—By the will of the late John Henry Schaefer of New York the Presbyterian and the German Hospitals of this city receive each a bequest of $10,000.

By the will of the late Mrs. Ida A. Whitman of Philadelphia contingent bequests of $5,000 each are made to the Presbyterian Hospital and the Episcopal Hospital to endow free beds in memory of her husband and a similar bequest of $2,500 to the Children's Hospital.

By the will of the late John G. Hees of Philadelphia the sum of $1,000 is bequeathed to the German Hospital.

By the will of the late Robert Wolf of Philadelphia the sum of $100 is bequeathed to the Jewish Hospital Association.

Fordham Faculty Dinner.—On Thursday evening of last week the Medical Faculty of Fordham University gave a dinner at the Hotel Astor in honor of the foreign lecturers in the International Extension Course on diseases of the nervous system which is being held this month. The guests of honor were Dr. Henry Head and Dr. Gordon Holmes of London and Dr. Nicolas Achucarro of Madrid. Drs. Alwyn Knauer of Munich and Carl Jung of Zurich, the other foreign lecturers in the course, were absent, having not yet arrived from Europe. Among the other guests were many of the most eminent neurologists of the country. The Rev. Dr. Thomas J. McClusky, President of Fordham University, presided, and Dr. James J. Walsh, Dean of the Medical Faculty, acted as toast-master. The speakers were Father McClusky, Father Hanselman, Provincial of the Society of Jesus; Dr. Henry Head, Dr. M. Allen Starr, Dr. Sears of the University of Vermont, Dr. M. J. Lewi, Judge O'Sullivan, and Paul Fuller, Esq., Dean of the Faculty of Law of Fordham University. The keynote of the addresses was internationalism in medical study as exemplified in the international extension course, which had been initiated somewhat in the nature of an experiment and which had from the first proved to be an unqualified success both in attendance and in the interest of the lectures. At the close of the speaking Dr. Maloney, to whom credit was given for originating the course, announced that the next series of lectures would be on the diseases of metabolism.

Clinical Physiology.—The Department of Physiology of the College of Physicians and Surgeons, New York, offers to practitioners in medicine a course in Clinical Physiology, which deals with the application of physiological principles and methods to problems of practical medicine. The course, which consists of fifteen weekly exercises, will be given by Dr. R. Burton-Opitz, Dr. F. H. Pike, Dr. Haven Emerson, and Dr. H. B. Williams, on Thursday afternoons from 3 to 5 o'clock, at the college, 437 West 59th street, beginning October 3. The fee for the course is $15, with a matriculation fee of $5 in addition. Applications may be made to Prof. Frederic S. Lee at the College of Physicians and Surgeons.

Mississippi Valley Medical Association.—The thirty-eighth annual meeting of this association will be held at the Hotel Sherman, Chicago, Ill., on October 22, 23, and 24, 1912, under the presidency of Dr. Louis Frank of Louisville, Ky. The orations in medicine and surgery will be delivered by Dr. C. G. Stockton of Buffalo, and Dr. George W. Crile of Cleveland. Details may be obtained from the secretary of the association, Dr. Henry Enos Tuley, Third street Annex, Weissinger-Gaulbert, Louisville, Ky.

Washington State Homeopathic Medical Society.—At the annual convention held in Tacoma on August 30 and 31, the following officers were elected: *President,* Dr. George H. Dow, Chehalis; *Vice-Presidents,* Dr. C. P. Bryant, Seattle, and Dr. E. F. Larkin, Bellingham; *Secretary,* Dr. George Walter Beeler, Seattle; *Treasurer,* Dr. Thomas J. Appleton, Seattle. The next annual meeting will be held in Seattle.

International Congress of Gynecology and Obstetrics.—This Congress, which has just closed its sessions in Berlin, elected Dr. J. Riddle Goffe of this city president, and voted to hold the next meeting in New York City in September, 1915. Among other Americans who attended the Berlin Congress and read papers were Dr. Parker Davis of Philadelphia and Dr. Hermann Boldt and Dr. Arthur Stein of New York.

Publications of the Tropical Diseases Bureau.—In November the Tropical Diseases Bureau, which replaced the Sleeping Sickness Bureau on July 1, will commence the publication of the *Tropical Diseases Bulletin* under the general editorship of the director, Dr. A. G. Bagshawe. Each number will consist of about fifty pages containing

classified summaries of the current literature of the tropical diseases; they will appear, as a rule, twice a month. The annual subscription price will be one guinea, post free. The publishers will be the Messrs. Baillière, Tindall & Co. of London. The tropical diseases of animals will be treated in a separate publication, the *Tropical Veterinary Bulletin*. This will appear quarterly from October and will be in charge of Mr. A. Leslie Sheather of the Royal Veterinary College, London.

Honorary Degrees Conferred by Fordham University.—The extension course for practising physicians in the study of nervous and mental diseases was opened at the Fordham University Medical College on September 9, to last for three weeks, women being admitted to the lectures for the first time, it is said, in the history of a Jesuit institution. Over a hundred and fifty physicians attended the opening. On September 11 the university conferred the honorary degree of LL.D. on Drs. Henry Head of London, Carl Jung of the University of Zurich, Nicolas Achucarro of Madrid, and Horatio Robinson Stover of Newport, R. I. Dr. Gordon Holmes of London was made a doctor of science. The new Fordham Clinic, the building and equipment of which have cost over $200,000, was also opened recently.

The Association of Life Insurance Medical Directors.—The twenty-third annual meeting of this Association will be held in New York City on Wednesday and Thursday, October 9 and 10 in the Board Room of the Mutual Life Building, 34 Nassau street. The following papers will be read: President's address, "Some Studies in Family History," by Brandreth Symonds, M.D., Chief Medical Director The Mutual Life Insurance Company of New York; "Further Report on Blood Pressure," by John W. Fisher, M.D., Medical Director the Northwestern Mutual Life, Milwaukee, Wis.; "Selection of Female Risks in Whom Hysterectomy and Ovariotomy Have Been Performed," by P. H. Ingalls, M.D., Assistant Medical Director the Ætna Life Insurance Company, Hartford, Conn.; "The Significance of Some Urinary Constituents," by J. Bergen Ogden, M.D., Assistant Medical Director the Metropolitan Life Insurance Company, New York City; "A Study of Chest and Abdominal Measurements in Relation to Build," by Faneuil S. Weisse, M.D., Medical Director the Mutual Life Insurance Company of New York. The annual dinner of the association will be held on Wednesday, October 9, at 6.30 P.M., at the University Club, Fifth avenue and 54th street, New York City. Further information regarding the meeting can be obtained from the secretary, Dr. William Evelyn Porter, 34 Nassau street, New York.

Obituary Notes.—Dr. George H. Cocks of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1882, a member of the American Medical Association, the New York State and County Medical Societies, the Academy of Medicine, and the New York Ophthalmological Society, assistant surgeon to the New York Eye and Ear Infirmary, and ophthalmologist to the Institute of Mercy, died at his summer home in Pleasantville, N. Y., on September 8, aged 51 years.

Dr. Horace Lewars died in the German Hospital at Philadelphia on August 26 as a result of uremia and paralysis at the age of 44 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1890. He was a retired officer of the First Regiment National Guard of Pennsylvania and during the Spanish-American War he took an active part in caring for the men when typhoid fever broke out in the camp at Chickamauga. He was a member of the Philadelphia Obstetrical Society.

Dr. William Dan Lamb of Lawrence, Mass., a graduate of Jefferson Medical College in 1846, died at his home on August 25, aged 88 years. He was closely identified with the early history of his native town, and served as an army surgeon during the Civil War.

Dr. Edouard Napoleon Fugere of McGregorville, N. H., a graduate of Laval University, Montreal, died on August 30, aged 49 years. He was a member of the medical staff of Nôtre Dame de Lourdes Hospital.

Dr. William T. Klein of New York, a graduate of the College of Physicians and Surgeons, New York, in 1895, and a member of the National Society for the Prevention of Tuberculosis and the Greater New York Medical Association, died at Sea Cliff, L. I., on September 7, aged 37 years.

Dr. Frank Edward Lewis of Albany, N. Y., a graduate of the Cleveland University of Medicine and Surgery in 1886, a member and vice-president of the New York State Homeopathic Medical Society, and attending physician to the Homeopathic Hospital of Albany, died at his home on September 10, after a long illness, aged 57 years.

Dr. Henry Strong Denison of Denver, Col., a graduate of the Johns Hopkins Medical School, Baltimore, in 1908, a member of the American Medical Association and of the Colorado State and Denver County Medical Societies, died suddenly at his home on August 28, aged 28 years.

Correspondence.

ANOPHELINES IN THE PHILIPPINE ISLANDS.

To the Editor of the Medical Record:

Sir:—May I venture to call the attention of your readers to an error in your Philippine letter dated June 14 in regard to the anophelines in the Philippine Islands? The writer says: "In view of the fact that no anophelines, even after most diligent search, have been found anywhere in the Philippine Islands (with the possible exception of one single specimen which is alleged to have come from the Philippines, and which is now in Washington)," etc.

I do not know where the writer got his information, but there could hardly be a greater misstatement. The anophelines are widespread and numerous throughout the islands, and include *Anopheles formosus* (Ludlow); *Myzomyia funesta* (Giles); *M. indefinita* (Ludlow); *M. ludlowii* (Theobald); *M. rossii* (Giles); *M. thorntonii* (Ludlow); *Stethomyia pallida* (Ludlow); *Myzorrhynchus barbirostris* (Van der Wulp); *M. pseudobarbirostris* (Ludlow); *M. sinensis* (Wiedemann); *M. vanus* (Walker); *Nyssorhynchus flava* (Ludlow); *N. fuliginosus* (Giles); *N. philippinensis* (Ludlow); *N. stephensi* (Liston); *N. theobaldi* (Giles); *Calvertina lineatus* (Ludlow).

The nomenclature is according to Theobald. In the eleven years I have been connected with the mosquito work for the Medical Corps, U. S. Army, I have handled thousands of anophelines from the Philippines, but *M. rossii* is one of those rarely sent in. There can hardly be said to be a

dearth of anophelines in the Philippines as a whole, but there are a few localities where they are seldom taken.

C. S. Ludlow.
Army Medical Museum and Library, Washington, D. C.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COST OF HOSPITALS—TROPICAL MEDICINE—THE AUSTRALIAN INSTITUTE—GOVERNMENT'S EXPEDITION TO THE NORTH—VITAL STATISTICS: LONDON RATES, RURAL RATES (ESSEX)—WOMEN'S CORPS CAMPING OUT—INSURANCE, MORE RESIGNATIONS—EXHIBITION—OBITUARY.

London, August 30, 1912.

Renewed attention has of late been directed to the cost of our London hospitals. On Tuesday the authorities of King Edwards Fund contributed some statistics of the expenditure in 1911, amplifying its annual report issued in April. There are 107 institutions connected with the fund, of which 17 are general hospitals, with an average of 100 beds in daily occupation and 15 with a lower average. The others are special: 4 for consumption, 5 for women, 6 for children, 3 epilepsy and paralysis, 5 ophthalmic, 12 cottage, 8 lying-in, and 32 unclassified. There were increases in the cost per bed and among out-patients amounting in 1911 to £9,600, against which it is stated must be set off economies of about £47,000 per annum effected since the first issue of the reports in 1904. It is said three factors tend to increase the expenditure: (1) tendency toward costly special treatments resulting from developments of medical science; (2) rise in prices; (3) danger lest success in effecting economies lead to slackness in the constant effort needed to maintain them.

It is important that where increase has occurred the committees should ascertain whether it has been unavoidable or due to preventable causes, particularly when the increase exceeds the average of similar hospitals. In the large general hospitals the increases occur under surgery and dispensary as well as maintenance (salaries and wages). In children's hospitals the increase in average cost is much heavier and more generally distributed over the different items of expenditure.

The Australian Institute of Tropical Medicine is making great progress. The Commonwealth Government has granted additional endowments to provide for extension of the work. From there new laboratories and special wards in the Townsville hospital are being erected. The universities of Sydney, Melbourne, Adelaide, and Brisbane will grant diplomas on the subject, leaving the teaching to the Institute. The Government will appoint representatives to control the arrangements jointly with the universities. The Institute has appointed Dr. Henry Priestley and Dr. Nicoll on the staff.

The report of the Australian Commonwealth's expedition to the Northern Territory to investigate tropical diseases shows that the occupation of the district by whites is mainly a medical problem. A fourth of the mortality is due to malaria. There are deaths from dysentery almost every year, besides epidemics which sometimes break out. Beriberi, ankylostomiasis, yaws, trachoma, and leprosy are also known, but generally have been so far sporadic. An important statement is that residents who live a reasonable life, taking adequate exercise and the precautions adapted to a tropical country, enjoy good health. Up to the present there is no evidence of the influence of the climate on the third generation, though it perhaps may have to be taken into consideration in the future. Dr. Breinl describes life on the stations as ideal with regard to health—an active outdoor life in the comparatively cool and dry winter experienced on the tablelands. But alcoholism is an enemy as much as malaria. The prominent lesson of the expedition is the necessity of skilled medical help. No precautions seem to have been in force in the mining settlements to restrain the spread of malaria or indeed any other condition. But the extirpation of malaria is not the only problem. The Territory is said to be exposed to infection from China and the Dutch Indies, and the sanitary conditions such that if once introduced tropical diseases would most likely assume an epidemic form. It is accordingly recommended that those diseases should be studied on the better known islands with a view of quarantine legislation. The necessity of this is indicated by the fact that one or two species of mosquitos known to abound in the Malay States have already been detected in the Northern Territory, showing that invasion from the East has actually taken place.

The facts mentioned in my last respecting the low birth-rate have since been illustrated and enforced by the return on Wednesday of the births and deaths during April, May, and June. In that quarter the births in England and Wales corresponded to a rate of 23.9 per 1000, which was 3.7 below the mean in the ten preceding second quarters and the lowest recorded in any second quarter. The natural increase of population by excess of births over deaths was 102,302, against 111,987, 119,154, and 105,812 in the second quarters of 1909, 1910, and 1911, respectively.

The deaths were equal to an annual rate of 12.7, or 1.7 below the mean in the ten preceding corresponding periods, and the lowest death rate recorded in corresponding quarters. London's rate was 12.4. The infantile mortality was at a rate of 89 per 1000 births, being 14 below the average in ten corresponding previous periods and the lowest on record. The deaths from epidemic diseases in the quarter totaled 8884.

Taking this closing month of August by itself, although it has been the wettest and coldest on record, still more favorable figures are reported and that especially in regard to infantile mortality, the difference between this year and last being chiefly due to the diminution of diarrhea, which is usually so excessive in summer. Many hundreds of children unquestionably owe their survival to the almost complete absence of summer heat, which so many of their seniors are lamenting.

Dr. J. C. Thresh, Medical Health Officer for Essex, has just issued his report for 1911, in which he touches on some of the above-mentioned facts, but in regard to his own district, one of the healthiest counties in the kingdom. The rural birth rate is there also falling and he says should have the attention of the State. He holds it to be affected by the dearth of good cottages and thinks owners might build them to return fair interest. But he admits that management and repairs may swallow up the returns, and the work should be done by public authorities.

Dr. Thresh reports that in his county the deaths from consumption are decreasing, but from cancer they have been continually on the increase and are now actually more numerous than from phthisis.

The Women's Sick and Wounded Convoy Corps

was founded about three years ago to provide efficient training for service in voluntary aid detachments in conformity with the requirements of the Red Cross Society. The training is based upon the R.A.M.C. system. The corps has gone into camp under its commandant-in-chief, Mrs. St. Clair Stobart, and in spite of the most adverse weather the members have carried out their duties with energy and even enthusiasm. Commandant Stobart requires the strictest discipline, and the daily program this week is exacting from reveille at 6 A.M. to "lights out" at 10:15 P.M. Night watches are kept from 10 to 2 A.M. and 2 to 6 A.M. The work of the camping out is no pretense. Everything is done by the members of the corps, even the pitching and striking of the tents and the digging of the camp fire trenches.

Another resignation from the Advisory Committee appointed under the National Insurance Act has taken place, that of Dr. Herbert Jones, Medical Health Officer for Herefordshire, one of the fourteen medical members who refused to resign at the request of the British Medical Association, declaring that they considered their duty "for the present" was to remain on the committee.

The medical staff of the Swansea Hospital informed the Board on Wednesday that they will be unable to give their services to persons insured under the Act when the medical benefit comes into operation except in cases of urgent necessity. Dr. Knight, on behalf of the staff, explained that these cases were accidents or serious diseases. Their only contention was with the Government which sought to impose on them heavy duties on impossible terms. It was said to concede their demands the Chancellor would have to find more than three millions, but Dr. Knight asked what would it cost to pay for the services now given gratuitously? He calculated in that hospital the surgical operations performed in a year, at five guineas each, would cost ten thousand, and that had hitherto been done gratuitously. The Board decided to hold a special meeting to discuss the matter.

An exhibition of modern appliances for the treatment of tuberculosis has been opened this week and will remain open for some time. It was organized by the Society of Medical Officers of Health and seems likely to succeed. Demonstrations and lectures are to be given at intervals. Hygienic measures, in relation to cookery, disinfection, open air shelters, are largely represented.

Mr. Clinton T. Dent, vice-president of the Royal College of Surgeons, senior surgeon to St. George's Hospital and chief surgeon to the London police, died on the 26th inst, aged 61 years. He took the M.R.C.S. in 1875 and proceeded to the fellowship two years afterward. He lectured in the school of St. George's when elected on the hospital staff, first on physiology, then on surgery. He became a member of several societies, contributing papers to them and to the journals. He was elected to the council of the college and in due course on the Court of Examiners. He also served for some time as examiner in surgery to the University of Cambridge, which in 1899 conferred on him the honorary degree of M.C. He wrote the "Nature and Significance of Pain," which you will probably remember. He translated and edited Billroth's "Clinical Surgery." The "Medico-Chirurgical Transactions," Heath's "Dictionary of Practical Surgery," Tuke's "Dictionary of Psychological Medicine," and the volumes of "Mental Science" were also indebted to his pen for illuminating articles. Besides his professional work, Mr. Dent was an explorer and mountaineer of distinction. He became president of the Alpine Club (1886-9). He conducted a series of explorations in the Caucasus. He wrote the volume on "Mountaineering" in the Badminton Library and many articles on Alpine as well as surgical subjects. In 1899 and 1900 he was in South Africa as an independent surgeon and the result was a series of letters on "Gunshot Wounds" in the *British Medical Journal*.

Mr. Edgar Jones, J.P., who died on the 26th inst. in his 103d year, was probably the oldest member of the profession as well as the senior magistrate. He took the membership of the Royal College of Surgeons in 1834 and practised for some years at Saffron Walden in Essex, but later he devoted himself to agriculture. In 1852 he was put on the Commission of the Peace and eventually became chairman of the Billericay Bench. King Edward sent him a telegram of congratulation when he attained his 100th birthday. A few months ago he met a centenarian woman and they exchanged reminiscences. Mr. Jones was a life abstainer from alcohol and tobacco. He retained his faculties in a remarkable degree.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

MEETING OF THE CANADIAN MEDICAL ASSOCIATION AT EDMONTON, ALBERTA.

TORONTO, Sept. 10, 1912.

THE annual meeting of the Canadian Medical Association took place this year on August 10, 12, 13 and 14 at Edmonton, Alberta. This is only the third time that the association meeting has been held in the West. Twenty-three years ago it was held in Banff, and in 1904 in Vancouver. The meeting at Edmonton was successful from many points of view; the attendance, considering the distance to be traveled before reaching Edmonton from Eastern Canada was excellent, and the papers generally were good.

Dr. H. G. MacKid, of Calgary, the president, gave an inspiring address filled with enthusiasm for the West and with wonderful predictions for its future. Dr. MacKid said in part that the outstanding need of the medical profession in Canada today was a closer and more thorough organization of the medical men in their respective district, county, and provincial associations, which as a result would find their fullest and proportionate representation in the National Medical Association. Reference was made to the passage of the bill which made interprovincial medical reciprocity possible, and a glowing tribute was paid to Dr. Roddick, of Montreal, for his untiring efforts to bring this about.

Dr. MacKid spoke of the value of the *Canadian Medical Association Journal* and said that, thanks to the labors of the finance committee of the past two years, an efficient journal had been established, which, under the able editorship of Dr. Macphail, had already won for itself a place in the periodical literature of the medical world. It was hoped that within a short time it might be made a weekly instead of a monthly. That, however, would depend upon the support given the association by the profession at large throughout the country.

Attention was also drawn to the affiliation of the various provincial associations with the Canadian

Medical Association, which had been carried through during the past twelve months. At present all of the provinces save one had declared themselves in favor of affiliation and had become affiliated.

After commenting on things done the speaker considered the needs of the future. According to him the great problem now is to get the Canadian Medical Association solidly cemented together. The establishment of the journal had been a long stride in this direction. The next step was to create a properly constituted central body, a sort of parliament, with proportionate representation from each province. First, however, county societies must be organized, and in those districts where none existed they must be created.

Dr. MacKid gave unstinted praise to the efforts of the American Medical Association to improve the standard of medical education, to uproot commercialism, and to abolish quacks and proprietary medicine and fake cures. In closing the speaker sketched in glowing and enthusiastic language the future of medicine in the West. Dr. A. E. Giles, London, Eng., gave the address in surgery.

A decidedly novel feature of the meeting was the fact that on the Sunday preceding the general sessions several pulpits in Edmonton were occupied by medical delegates. Sir James Grant, of Ottawa, occupied the pulpit of Knox Church and delivered a striking health homily from the text, "Turn ye, turn ye; why will ye die?" Sir James discoursed eloquently on health matters and especially on tuberculosis, and wisely pointed out that in a new city as Edmonton was it was important that the utmost care should be taken in its drainage facilities, as defects in drainage and sewer utilities was a cause of many diseases. Dr. Bruce Smith, of Toronto, preached a sermon on health in the Metropolitan Methodist Church, taking as his text, "It doth not appear what we shall be. The earth is the Lord's and the fullness thereof."

Among papers of interest read in the section was one that attracted marked attention by Dr. E. Ryan, superintendent of the Rockwood Hospital at Kingston, Ont. This paper, entitled "Seven Years' Advance in the Ontario Hospital for Mental Diseases," was somewhat of an indictment of the manner in which mentally deranged persons are treated in some localities and indeed were treated in Ontario seven years ago. Dr. Nicholls, of Edmonton, in discussing the paper, said that he had been informed by the Attorney-General that the only asylum in Alberta was so crowded with people of a low criminal grade that it left no room for anyone unless dangerously insane. According to the speaker, so far as the management and care of the insane was concerned in Alberta, they are now where Ontario was twenty years ago and not where it was seven years ago. He pleaded that the public take more interest in the matter and compel the government of Alberta to make more adequate provision for the cure of the mentally sick in the province.

The meeting was chiefly distinguished perhaps by its health sermons and by its popular lectures. On the evening of August 14 Prof. J. George Adami, of Montreal, delivered an address, taking as his text "The Sins of the Fathers." It was, in fact, an excellent scientific disquisition on heredity. He attacked the modern popularly accepted doctrine that acquired conditions are not inherited, and as a corollary that the germ cells are unaffected no matter what vicissitudes are undergone by the body at large, or rather, perhaps, by the body of the parent-at-large. This is to say that the sins of the fathers do not tell upon the children. These teachers prophesy that no matter how the parent ill treats his body prior to conception the progeny is unaffected; a man may have tuberculosis or syphilis, and provided he does not give the disease to the mother and so bring about infection of the fetus in the womb, the child is likely to be as strong and healthy as that of a perfectly sound parent. Adami stated emphatically that he was sufficiently old-fangled to repudiate this new-fangled "Weismannism," and he still held the belief that the sins so-called of the parents against the body, or at least a very important series of such sins, do influence the progeny to his hurt, and, what is more, he believed that these new-fangled ideas had their origin in the narrowness, or it might be said in the Chauvinistic provincialism of the zoologists. Adami went on to show that inheritance of disease was not everything, from the point of view of eugenics, the terrible effects of congenital disease and more particularly of infections conveyed to the growing individual while in the womb or during parturition must be considered. When it is accepted that at least half of gynecological practice is due to gonorrhea and its results, that a large proportion of the cases of infantile blindness is of gonorrheal origin, that as demonstrated by the Wassermann test, practically all cases of locomotor ataxia, and nearly all cases of general paralysis of the insane are of syphilitic origin; when we know that most cases of multiple successive abortions are syphilitic, and recognize the puny, miserable parodies of humanity doomed in most instances to an early death, that too often are the result of syphilitic disease in the parent; when we realize the preventable ills that follow in the train of these venereal diseases, the speaker said he wholly agreed that the time had come when we should no longer refer to these matters by circumlocutions, when for the good of the coming generations we should openly wage war against gonorrhea and syphilis, and above all should for the safety and welfare of our children instruct them as to the dangers they must ward against, not merely on account of their own health and happiness, but for the sake of the generations yet unborn.

Prof. H. A. McCallum, of London, Ontario, was elected president and London, Ontario, was selected as the next place of meeting. The Executive Council was elected as follows: Drs. Whilland, Edmonton; Findlay, Montreal; Adami, Montreal; Halpenny, Winnipeg; Reeve, Toronto; McKechnie, Vancouver; Small, Ottawa; Kennedy, Macleod; Daniels, St. John, N. B.; Madre, Halifax; Archibald, Montreal; Primrose, Toronto; Conroy, Charlottetown, and Young, Saskatoon. Dr. H. G. MacKid, Calgary, as president of the association will be a member of the committee *ex officio*. With true Western hospitality the medical men who attended the meeting were entertained in various ways. Trips were arranged to points of interest in the vicinity of Edmonton—vicinity being a broad term in that land of immense distances. Visits were made to points in the Rockies, only a question of a hundred miles or so, and a good impression was created of the great Northwest. The meeting was eminently successful both from the scientific and social viewpoints.

Progress of Medical Science.

Boston Medical and Surgical Journal.

September 5, 1912.

1. The Use of Lactic Acid Soured Milk and Lactic Acid Bacilli in Pulmonary Tuberculosis. P. C. Bartlett and C. V. Murphy.
2. Two Cases of Diverticulum of the Bladder Treated by Operation. A. L. Chute.
3. Present Status of Salvarsan. A. Post.
4. Two Cases of Orchitis Due to Mumps Treated by Operation. G. G. Smith.

1. Use of Lactic Acid Bacilli in Pulmonary Tuberculosis.—P. C. Bartlett and C. V. Murphy state that every clinician who has concerned himself extensively with the care of tuberculous patients has been impressed with the prostrating effect of the obstinate diarrhea, alternating very often with intervals of constipation, which is a not infrequent complication of well established, or advanced pulmonary tuberculosis. That the large percentage of these cases are functional only has been indicated by a somewhat extensive study of the feces in the laboratories of the Rutland State Sanatorium, and their toxic origin is strongly suggested. It is in connection with this type of individual, as well as in cases of actual tuberculous enteritis that the employment of lactic acid soured milk has afforded the maximum benefit, both as a dietary measure in support of energy and in tissue repair, and as an agent favorably modifying the symptoms and controlling the diarrhea. Its range of usefulness extends over almost the entire field of gastrointestinal affections encountered in connection with sanatorium work.

2. Diverticula of the Bladder.—A. L. Chute reports two cases of diverticulum of the bladder successfully treated by operation. The type presented by the two cases differed essentially from the clearly congenital double bladders, on the one hand, and also from the little herniæ of the bladder that are directly due to pressure and usually arise near the vertex. Diverticula, such as those in the reported cases cannot strictly be called congenital, yet the author believes they always have their origin in the little pits that one sees from time to time just to the outside of the ureteric orifice, and which are undoubtedly faults or anomalies in the development of the bladder. Embryologically buds from the fetal ureter, which might easily lead to such little pockets, are supposed only to arise to the inner side of the ureter, while these are seen on the outer side. Many writers note the frequency with which diverticula appear just outside the ureter, but the author has seen no explanation offered for this. He believes the most probable explanation lies in the little congenital pits or pockets. These are not confined to males. Their presence is not in itself sufficient to bring about the formation of a diverticulum. There must be the determining agent as well, such as an increase in the intravesical pressure. This may be due to obstruction at the bladder outlet, or anywhere along the urethra, or a sharp cystitis, attended with violent bladder spasms, may be sufficient.

3. Present Status of Salvarsan.—A. Post concludes that salvarsan is the most rapid and powerful antisyphilitic known. It is not without its dangers which are sufficient to induce caution in its use, but not to cause its abandonment. It is not yet possible to promise absolutely a cure. One should not urge its use upon those who are impressed by its possible ill effects. It should be used in conjunction with mercury in all cases in which a diagnosis can be made before general symptoms appear. It should be used in all cases in which patients are not progressing well under ordinary treatment in any stage. It should be used in all cases in which patients are an especial danger to the community. It should not be used in maximum doses, but rather in repeated medium doses and in exceptional cases in repeated minimum doses.

4. Surgery of Orchitis Due to Parotitis.—G. G. Smith reports two cases of orchitis of this nature on which he operated with the primary object of preventing, if possible, the atrophy which so frequently follows this affection. The method employed was based upon the theory that atrophy results from the increased intratesticular pressure caused by the inflammation. Relief of this tension obtained by slitting the tunica albuginea restores the circulation and preserves the testicle.

New York Medical Journal.

September 7, 1912.

1. Yellow Fever a Strictly Human Disease. A. Agramonte.
2. Pneumonia in Children. H. Lowenburg.
3. The Wassermann Test. D. M. Kaplan.
4. Vesical Neoplasms. J. F. McCarthy.
5. Ten Sex Talks to Girls. I. D. Steinhardt.
6. Endourethral Chancre. E. H. Marsh.
7. A Completed Treatment for Tonsillitis. F. Griffith.
8. Massive Tuberculosis of the Liver. D. Felberbaum.
9. The Cinematograph as an Aid to Medical Education and Research. R. Matas.

1. Yellow Fever a Strictly Human Disease.—A. Agramonte states that the hypothesis is unsupported which avers that yellow fever may attack the lower animals and that thereby the causative agent may continue to spread or be kept alive for considerable periods without attacking human beings living in the same territory. Numerous attempts have been made to inoculate the lower animals with this disease, but these attempts have been unsuccessful except in one instance, the inoculation of a chimpanzee by Thomas, in Brazil. The author has inoculated animals with venous blood, fecal matter, and "black vomit" from human cases, and has even applied infected mosquitos to the abdomen of rhesus monkeys, without in any instance transmitting the disease. In view of these facts and inasmuch as the mosquito's life is not shortened by carrying the virus and does not seem to be in the least affected by the latter, the author concludes that yellow fever is strictly a human disease.

3. Wassermann Reaction.—D. M. Kaplan concludes that there are diseases other than lues giving positive reactions. The old method of amboceptor standardization does not consider all the obstacles that it is designed to overcome. The aging of the antigen is capable of producing inhibition in doses smaller than ascertained in the original gauging, and should receive attention on the day of the test. The patient's serum ought not to be older than forty-eight hours. Old sheep cells develop anticomplementary powers.

4. Vesical Neoplasms.—J. F. McCarthy presents the following conclusions, which, in the light of recent advances, would appear to serve as a more or less adequate working basis in the treatment of tumors of the bladder, though in reality each case should be considered on its individual merits. The Oudin spark treatment (cystoscopic) applies to small or moderate size growths, single or multiple, particularly the latter, which are accessible and apparently of a benign character. In the absence of a reasonably prompt effect, such treatment should not be prolonged. Except in the unusual case in which pronounced hematuria obscures the view, the method will supplant the suprapubic operation of coning the mucosa. The application of the spark should not be made in a cloudy field, as in such event it is inexact and dangerous. Growths of an infiltrating character and suspiciously malignant should very promptly be removed by resection through the entire bladder wall at least two centimeters beyond the mass, and when in close proximity to the ureteral orifice should include ureter transplantation. In the case of a very great number of outgrowths in the bladder which, while benign, are, from their very multiplicity, not amenable to the spark treatment, one should not forget that this same treatment may with much effectiveness be directed via the suprapubic opening. It is the author's hope that the employment of the d'Arsonval spark may offer something even of a palliative nature in such cases as appear to be beyond reach.

8. Massive Tuberculosis of the Liver.—D. Felberbaum notes that this condition is usually secondary to intestinal tuberculosis, and reaches the liver by way of the portals. The first step is a tuberculous pylephlebitis and thrombosis of the endohepatic branches, and later on tuberculous granulation tissue is deposited. A number of these granulomata coalesce and form conglomerate tubercles. These deposits are usually multiple and may soften down, giving rise to a tuberculous abscess, which may eventually discharge into a bile duct, similarly to a caseous focus in the lung, rupturing into a bronchus. The nodules appear as white masses of various sizes and shapes, surrounded by a thin fibrous capsule. The adjacent liver substance is compressed and may become pigmented. They resemble very much gummata, but may also simulate neoplastic growths, as in the case to be described. The symptomatology is very definite, no case having ever been diagnosticated during life. The liver may be enlarged; tumor masses have been felt during life. Jaundice does not occur. The cases have all been characterized by gradual emaciation, but on the whole, the symptom complex is masked by the primary affection. There are two cases on record in which the process in the liver was apparently primary, no other tuberculous foci being discovered. The disease is slightly more frequent in children, probably on account of the frequency of intestinal tuberculosis. The case reported by the author exemplifies the difficulties of the diagnosis *intra vitam,* especially in that it was considered to be a case of carcinoma of the stomach and liver, tuberculosis not having been suggested as a possible diagnosis by any one of the many who examined the patient during life. Even after the specimens were obtained, the condition was considered by nearly all who saw it as a malignant growth.

3. Transverse Myelitis Type of Poliomyelitis.—A. L. Skoog describes the pathological findings at autopsy of a patient dying from acute poliomyelitis of the *foudroyant* type. He notes that the perivascular tissue, which must not be confused with the adventitia, comes first in the frequency and severity of pathological changes. The adventitia is a worthy second and its cells and fibers may be completely disintegrated by the thick invasion of cells. All coats of the veins are frequently involved. The large arteries have only their perivascular structures invaded; the moderate sized ones have the adventitia also invaded, and the small arteries or arterioles may have an infiltration of intima, elastica and muscularis as well as the frequently involved adventitia. It is possible that some of these severely involved vessels have necrosing tunics with resulting thromboses or ruptures of the walls. The author believes that the infiltrating cells give evidence of a defensive process, and all indicate the particular quantitative localization of the virus of acute poliomyelitis in the tissues.

4. Spinal Cord in Pernicious Anemia.—R. N. Willson reports a case of pernicious anemia with marked nerve center involvement and an interesting family history, and describes the complications on the part of the nervous system in this disease. It is well to remember that there are spinal cord and perhaps brain changes in every case of true pernicious anemia and the nervous symptoms may sometimes prevent its prompt recognition. The spinal cord lesions consist of a combined sclerosis of the posterior and lateral columns, the former sometimes being alone affected and producing the clinical picture of tabes. The lateral columns are never involved by themselves. A considerable number of cases have been reported in which the anterior horns were involved, but this is a late development in the disorder. In the case reported there was a very striking clinical indication of a pathological intestinal process dating back to childhood, and it seems evident that this toxemia led up to, if it is not absolutely demonstrated to be the direct cause of, the later symptoms. The family history suggests a possible hereditary luetic influence, since one sister of the mother died in an advanced stage of locomotor ataxia, while two other aunts and the mother herself suffered also from conditions which might have thus originated.
